Nitric Oxide

1 General Comments about Nitrogen Oxides

Nitrogen commonly forms several different oxides with oxygen, depending on the state of oxidation of the central atom, nitrogen. The state of oxidation of nitrogen can be +1, +2, +3, +4, +5, or +6. This chapter is on nitric oxide, NO. Nitric oxide is one of the thermodynamically unstable oxides and has a tendency to decompose to dinitrogen and dioxygen.

Oxygen is the third most abundant element in the Universe after hydrogen and helium. Wherever it is available in the presence of nitrogen and exposed to cosmic radiation, one must assume that nitrogen oxides may form and condense in colder parts of the system. Therefore, nitrogen oxides, including nitric oxide, are expected to be present in the solid phase in giant gas planets and “icy” grain mantles of comets and interplanetary particles.

Coverage of nitrogen oxides had to be spread out over seven chapters because a single chapter devoted to the topic would have been unwieldy and made it more difficult for readers to find information on a specific compound; in addition, such an approach would have made it difficult to arrange 30 chapters among 5 subvolumes in such a way that each subvolume was about the same size. Briefer chapters made our task much easier. The other six chapters in this series are titled “Nitrogen Oxides,” “Nitrous Oxide,” “Dinitrogen Trioxide,” “Nitrogen Dioxide,” “Dinitrogen Tetroxide,” and “Dinitrogen Pentoxide.”

2 Nitric Oxide

Nitric oxide, NO, also called nitrogen(II) oxide, nitrogen monoxide, mononitrogen monoxide, and CAS RN [10102-43-9], is a colorless gas. As soon as it comes into contact with air (or oxygen) it becomes oxidized (autoxidized) to nitrogen dioxide, NO₂, a dark red gas, which makes a potential NO leak more visible and causes the gas to be more toxic if inhaled.

Nitric oxide, NO, is a free radical similar to NO₂ and is an important intermediate in the chemical industry. Nitric oxide is a byproduct of hot combustion processes in air, as in automobile and jet engines and fossil fuel power plants, and is produced naturally in electrical discharges of lightning in thunderstorms. In most cases, it autoxidizes in air in the presence of excess oxygen and converts to nitrogen dioxide as soon as it has cooled off. It is an essential part of the nitrogen cycle on Earth.

It is unlikely that nitric oxide, in particular liquid nitric oxide, will ever be used as a rocket propellant because of its explosion hazard. However, nitric oxide is needed for the preparation of mixed oxides of nitrogen and so must be included here in this

book on rocket propellants, even if it is rarely handled in its pure state. Exothermic nitric oxide decomposition has been used to create hot gases with a chemical composition similar to that of hot air for studies of ablation in simulating atmospheric reentry of space capsules in a high-temperature wind tunnel [1]. It was in the preparation for one of those experiments that a tank with liquid nitric oxide exploded and caused substantial damage. This accident triggered a series of safety investigations. Nitrous oxide had been evaluated for the same application. Nitric oxide has been used as a chemical laser propellant, and this book contains information on many other energetic chemicals that are of interest for chemical lasers as well as rocket propellants.

Nitric oxide is an intermediate in the production of dinitrogen tetroxide and nitric acid, widely used rocket propellant oxidizers. Nitric oxide and other oxides of nitrogen derived from it are important atmospheric pollutants and play a key role in atmospheric nitrogen chemistry relating to smog formation and ozone destruction. Therefore, the kinetics of NO formation and decomposition under the influence of a wide range of energy sources (heat, UV radiation, electron bombardment, gamma radiation, atomic oxygen collisions) have been extensively investigated. Some of these atmospheric chemistry studies contain information that is also useful for the handling and purity control of nitric oxide to be converted to rocket propellant. The main mechanism of abiotic atmospheric nitrogen fixation, converting dinitrogen to a form that can be digested by all plants (even those without nitrogen-fixing *azotobacter* bacteria in their root nodules) is through nitric oxide formed in lightning strikes.

Nitric oxide is one of the few chemicals that has an entire journal title and a society dedicated to its chemistry, mostly for its role as a signaling chemical in nerve conduction. *Nitric Oxide* (ISSN 1089-8603) is a peer-reviewed scientific journal of the Nitric Oxide Society. The journal covers the broad field of nitric oxide research and includes basic and clinical topics such as cell biology, molecular biology, biochemistry, immunology, pathology, genetics, physiology, pharmacology, and disease processes. Nitric oxide is a vasodilator, and well-known blood-pressure-lowering pharmaceuticals such as nitroglycerin and amyl nitrite are precursors to nitric oxide in the bloodstream.

3 Preparation of Nitric Oxide

The predominant method for the production of nitric oxide is the catalytic combustion of ammonia over a platinum gauze (Ostwald process):

but under the conditions of this process, the nitric oxide is immediately oxidized with additional oxygen to form nitrogen dioxide, which is then absorbed in water to form nitric acid. For the preparation of small amounts of NO in the laboratory, a convenient method is the reaction of copper shavings with nitric acid:

It sometimes helps to purify the NO before converting it to NO₂ [2]. This report also describes methods for the detection and measurement of residual impurities in the final products.

4 Physical Properties of Nitric Oxide

4.1 Freezing Point and Phase Behavior of Nitric Oxide

Table 1 gives a summary of various freezing point (melting point) and boiling point data reported for nitric oxide in the literature.

Table 1: Freezing point (melting point) and boiling point of nitric oxide.

Property	Temperature		Author	Year
	K	°C		
Melting point	109.49	−163.66	Johnston and Giauque [3]	1929
	109.88	−163.27	Goldschmidt [4]	1923
Boiling point	121.36	−151.79	Johnston and Giauque [3]	1929
	121.87	−151.28	Goldschmidt [4]	1923

The triple point temperature of nitric oxide is at 109.49 ± 0.05 K, and the triple point pressure is 16.438 ± 0.004 cm Hg.

4.1.1 Phase Behavior at Very High Pressures

At pressures above 1.5 GPa, NO undergoes a disproportionation reaction, leading to N₂O and N₂O₄. At even higher pressures, many nitrogen oxides transform to a remarkably stable isomer, nitrosonium nitrate NO⁺NO₃[−]. It was not possible to extend thermal conductivity measurement beyond 13.76 MPa (2000 psia) because of incipient disproportionation of NO into NO₂ and N₂.

The chemistry of nitric oxide under static high-pressure conditions has been studied using diamond anvil cells and spectroscopic methods [5, 6]. Pressurized samples that were warmed rapidly to room temperature underwent facile disproportionation to form N₂O, N₂O₃, N₂O₄, and NO⁺NO₃[−]. Nitric oxide maintained at 80 K was observed to react at ca. 2.5 GPa to form N₂O and NO⁺NO₃[−]. The complex chemistry of nitric oxide is best explained in terms of two competing primary reaction mechanisms: **(1)** direct formation of N₂ and O₂ and **(2)** disproportionation to form N₂O and NO⁺NO₃[−]. The disproportionation reaction, which is favored under higher-temperature conditions, releases two-thirds of the total energy content and is believed to be important in the early chemistry accompanying shock-initiated detonation of nitric oxide.

4.2 Density of Nitric Oxide

The density of gaseous nitric oxide at 298 K is 1.3402 g/L, and the density of liquid nitric oxide at 123 K (−150.2 °C) is 1.269 g/mL. The density of frozen nitric oxide at 78 K is 1.556 g/cm³ [7].

4.3 Compressibility of Gaseous Nitric Oxide

The virial coefficients B of the equation of state

$$PV = RT + BP$$

were determined for nitric oxide and nitrous oxide [8]. The virial coefficient B of nitric oxide in the temperature range 121 to 307 K as a function of temperature and pressure can be expressed by the equation

$$B = 20 + 5881.5/T - 5.7639 \times 10^6/T^2 + 8.4301 \times 10^{10}/T^4 - 9.2783 \times 10^{14}/T^6$$

where B is the virial coefficient in cm³/mol, and T is the temperature in kelvin. Later examination by other investigators showed that the Johnston and Weimer [8] values for N₂O were consistently too low and for NO the values were consistently too high. Vapor density and compressibility measurements of NO at high pressures and temperatures near the boiling point were performed in an effort to determine whether NO associates to a dimer under those conditions. PVT measurements alone were not able to conclusively answer that question. The unusually steep rise in the heat capacity curve of liquid nitric oxide indicated that dissociation of the polymerized molecules was proceeding rapidly in the liquid phase just below the boiling point. This made it unlikely (although not impossible) that any appreciable trace of association remained in the gas phase because of the much lower concentration of the molecules in the latter.

4.4 Vapor Pressure of Nitric Oxide

The sublimation vapor pressure of frozen nitric oxide in a range between 65 K = −208 °C = 0.5 μm Hg and 95 K = −178 °C = 10 mm Hg pressure can be expressed by the following equation:

$$\log P = -(877.2/T) + 10.2368$$

where P is the vapor pressure in mm Hg, and T is the temperature in kelvin [9].

The vapor pressure of frozen nitric oxide can be calculated from the following equation [3]:

$$\log p = -867/T + 0.00076T + 9.05125$$

where p is the pressure in cm Hg (intl.) and T is the temperature in kelvin, and for liquid nitric oxide:

$$\log p = -776/T - 0.002364T + 8.562128$$

where again p is the pressure in cm Hg (intl.) and T is the temperature in kelvin. See also [8].

4.5 Viscosity of Nitric Oxide

The viscosities of gaseous nitric oxide (372–1015 K) and gaseous nitrous oxide (372–733 K) were measured using a capillary-flow viscometer in comparative mode, calibrating the instrument with nitrogen gas [10]. Smoothed viscosity data for nitric oxide are shown in Table 2.

Table 2: Smoothed dynamic viscosity data for gaseous nitric oxide.

Temperature K	Dynamic viscosity		
	mPa s	$\mu\text{N s m}^{-2}$	μPs
400	0.02405	24.05	240.5
500	0.02855	28.55	285.5
600	0.03266	32.66	326.6
700	0.03644	36.44	364.4
800	0.03996	39.96	399.6
900	0.04326	43.26	432.6
1000	0.04637	46.37	463.7

Data source: [10]

The viscosity of gaseous nitric oxide as a function of temperature can be expressed by the equation

$$\eta = \frac{aT^{1/2}}{1 + b/T + c/T^2}$$

where η is the viscosity in $\mu\text{N s m}^{-2}$, T is the temperature in kelvin, and a , b , and c are constants: $a = 1.740 \mu\text{N s m}^{-2} \text{ K}^{-1/2}$, $b = 191.9 \text{ K}$, and $c = -5276 \text{ K}^2$. See also [11].

4.6 Surface Tension of Nitric Oxide

An application of the corresponding states principle to the surface tension of nitric oxide can provide an interpretation of the unique surface tension behavior of NO: the

surface tension decreases when the temperature increases, as expected, but it does so at a substantially higher rate than is usually observed with other substances [12].

The surface tension of three binary liquid mixtures of NO with Kr, CH₄, and C₂H₄ was determined in the temperature range 102 to 119 K, depending on the ability of the molecules of one component to associate with each other [13]. The surface tension of liquid nitrous oxide as a function of temperature can be expressed by the equation

$$\eta = 69.72 - 0.3840 T$$

where η is the surface tension in mN/m, and T is the temperature in kelvin. This work also contained the surface tensions of the pure compounds (Table 3). Mixtures of NO with hydrocarbons would probably be detonable, but nowhere do the authors alert the reader to this potential hazard. It seems the apparatus was still in one piece at the time they finished their surface tension measurements. See also [14].

Table 3: Surface tension of liquid nitric oxide.

Temperature, K	Surface tension, mN/m
112.6	26.51
113.0	26.33
113.5	26.12
114.1	25.88
115.0	25.61
116.0	25.14
117.4	24.55
118.7	24.12
120.1	23.64
121.0	23.28

Data source: [13]

4.7 Velocity of Sound in Nitric Oxide

The velocity of sound in gaseous $\text{N}_2\text{O}_2 \rightleftharpoons 2\text{NO}$ was determined at various temperatures [15]. The velocity of sound data obtained were used to calculate the mol fractions of N_2O_2 and NO in the $\text{N}_2\text{O}_2 \rightleftharpoons 2\text{NO}$ mixtures. From these data the equilibrium constants of dimerization were calculated for the system at various temperatures and compared to the literature. The $\text{N}_2\text{O}_2 \rightleftharpoons 2\text{NO}$ system was studied at approximately 270 K (3 °C). With a tube length of 0.986 m and a travel time of 6.14 ms (for twice the distance of the tube), the velocity in $\text{N}_2\text{O}_2 \rightleftharpoons 2\text{NO}$ was determined to be 321.2 m/s. At this temperature, it was determined that the system was 95% monomeric NO. At a pressure of 22.3 Pa (168.0 mm Hg), the K_p was determined to be 3.99 atm.

4.8 Thermal Conductivity of Gaseous Nitric Oxide

A section in *Encyclopedia of Oxidizers*, in the chapter “Nitrous Oxide,” lists the thermal conductivities of nitric oxide at atmospheric pressure for a temperature range from 120 to 380 K in comparison to those of nitrous oxide and dioxygen, based on data from [16].

The thermal conductivity of gaseous nitric oxide was determined in an apparatus that consisted of two concentric spherical shells whose temperatures were measured while a known radial thermal flux passed between them [17]. Figure 1 illustrates the effect of pressure and temperature on the thermal conductivity of nitric oxide. It was not possible to extend the data measurement beyond 6.88 MPa (1000 psia) at 444 K (171.1 °C = 340 °F) or 13.76 MPa (2000 psia) at 277.6 K (4.44 °C = 40 °F) because of incipient disproportionation of NO into NO₂ and N₂.

The thermal conductivity of liquid nitric oxide at its normal boiling point was estimated to be 0.176 W m⁻¹ K⁻¹ (4.2×10^{-4} cal s⁻¹ cm⁻¹ °C⁻¹) [18].

Figure 1: Effect of pressure and temperature on thermal conductivity of gaseous nitric oxide. (Reproduced and modified from [17].)

4.9 Thermodynamic Properties of Nitric Oxide

A complete set of thermodynamic data for nitric oxide can be downloaded from the NIST Chemistry WebBook web site [19]. Another set of data is available in the JANNAF tables.

4.9.1 Heat Capacity of Nitric Oxide

The heat capacity of gaseous nitric oxide as a function of temperature can be expressed by the Shomate equation

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + E/\tau^2$$

where C_p is the heat capacity in $\text{J mol}^{-1} \text{K}^{-1}$, τ is the temperature in kelvin divided by 1000: $\tau = \text{K}/1000$, and A, B, C, D, and E are constants listed in Table 4 for two different temperature ranges.

Table 4: Thermodynamic property polynomial equation coefficients for nitric oxide gas.

Temperature range, K	298–1200	1200–6000
A	23.83491	35.99169
B	12.58878	0.957170
C	−1.139011	−0.148032
D	−1.497459	0.009974
E	0.214194	−3.004088
F	83.35783	73.10787
G	237.1219	246.1619
H	90.29114	90.29114

Data source: [19]

Uncorrected, raw heat capacity data for solid and liquid nitric oxide are listed in Table 5.

4.9.2 Enthalpy of Formation of Nitric Oxide

The standard enthalpy of formation of gaseous nitric oxide is $+90.29 \text{ kJ/mol} = +21.58 \text{ kcal/mol}$ (JANAF). A positive enthalpy of formation explains the explosive potential of liquid and gaseous nitric oxide, which has been the cause of industrial accidents during isotope separation and hot gas generation for supersonic wind tunnels. The standard enthalpy of formation of gaseous nitric oxide as a function of temperature can be expressed by the equation

$$H^\circ - H^\circ_{298.15} = A\tau + \frac{B\tau^2}{2} + \frac{C\tau^3}{3} + \frac{D\tau^4}{4} - \frac{E}{\tau} + F - H$$

Table 5: Uncorrected heat capacity data for solid and liquid nitric oxide.

Physical state	Temperature, K	Heat capacity, cal mol ⁻¹ °C ⁻¹	Heat capacity, J mol ⁻¹ K ⁻¹
Solid	15.57	0.935	3.912
	17.75	1.303	5.452
	19.51	1.59	6.653
	22.27	1.964	8.217

	117.35	17.329	72.505
	118.86	17.935	75.040
	120.56	18.667	78.103

Data source: [3]

where H° is the standard enthalpy in J mol⁻¹, τ is the temperature in kelvin divided by 1000: $\tau = K/1000$, and A, B, C, D, E, F, and H are constants listed in Table 4 for two temperature ranges. See also [20].

4.9.3 Heat of Fusion of Nitric Oxide

The heat of fusion of nitric oxide at its natural melting point (109.49 K = -163.66 °C) is 2299 ± 4 J/mol (549.5 ± 1 cal/mol) [3].

4.9.4 Heat of Evaporation of Nitric Oxide

The heat of evaporation of nitric oxide at its normal boiling point (121.36 K) is 13.776 ± 0.014 kJ/mol (3292.6 ± 3.3 cal/mol) [3].

4.9.5 Entropy of Nitric Oxide

The standard entropy of gaseous nitric oxide as a function of temperature can be expressed by the equation

$$S^\circ = A \times \ln(\tau) + B\tau + \frac{C\tau^2}{2} + \frac{D\tau^3}{3} - E/(2\tau^2) + G$$

where S° is the standard entropy in $\text{J mol}^{-1} \text{K}^{-1}$, τ is the temperature in kelvin divided by 1000: $\tau = K/1000$, and A, B, C, D, E, and G are constants listed in Table 4 for two temperature ranges. The entropy of gaseous NO at 298 K and 1 bar is $210.76 \text{ J mol}^{-1} \text{K}^{-1}$.

4.10 Molecular Properties, Structure, Dipole Moment, Molecular Orbital Calculations of Nitric Oxide

4.10.1 Molecular Structure of Nitric Oxide and Its Dimer

It is not commonly known that nitric oxide forms a dimer in the liquid state, dinitrogen dioxide, similar to dinitrogen tetroxide, but with a weaker association between the two molecules. The dimers of molecules that exist in monomer and dimer forms are also called homodimers. The study of the molecular structure of NO is revealing because NO is one of the simplest molecules capable of forming dimers but not larger aggregates. This compound is known to be moderately associated in the gaseous state but to be wholly dimerized in the solid and partially associated in the liquid states. The question of the dimerization of nitric oxide in the gas phase was first examined in the light of the principle of corresponding states, applied to the second virial coefficient. This dimerization is expressed in some physical properties, such as surface tension of liquid nitric oxide.

The molecular structure of NO and its dimer have been thoroughly investigated, mainly for its involvement in atmospheric pollution and natural nitrogen fixation, but also in the hope of identifying more energetic forms of NO and its oligomers that might be stable enough to be used as rocket propellants. The N_2O_2 dimer has been studied more extensively due to the discovery that NO regulates many physiological processes in the body. Some investigators have examined N_2O_2 dissociation energy while others have concentrated on the method and shape of bonding or critical point properties.

The existence of the $(\text{NO})_2$ dimer has long been invoked from anomalous Pressure-Volume-Temperature (PVT) behavior, thermodynamic properties, and second virial coefficient measurements. Its IR, Raman, UV, X-ray diffraction, and mass spectra have been observed. It was determined that N_2O_2 does in fact exist and is a very flexible molecule [21]. From the temperature dependence of the IR

and UV intensities, obtained in liquid NO at temperatures in the range 100–140 K, the heat of dimerization was measured as -2.45 ± 0.2 kcal/mol (115–126 K) and -2.25 ± 0.1 kcal/mol (100–140 K), respectively.

It has been suggested that it is the NO dimer, N_2O_2 , that reacts with O_2 in the reaction

The dimer $(\text{NO})_2$ can also be detected at room temperature in compressed gaseous NO. From the temperature dependence of the UV absorption intensity the enthalpy change for the reaction $2\text{NO} \rightarrow (\text{NO})_2$ was calculated to be -4.48 ± 0.29 kJ/mol (-1.07 ± 0.07 kcal/mol) at 273–364 K, and the standard enthalpy of formation would be $\Delta H_f^{316} = 176.1 \pm 0.5$ kJ/mol (42.09 ± 0.11 kcal/mol) [20].

Microwave and radiofrequency spectra for $(\text{NO})_2$ using the technique of molecular beam electric resonance spectroscopy were used to determine rotational, nuclear quadrupole coupling and spin-rotation constants of the ground electronic state treated as a singlet state [22]. From these data $(\text{NO})_2$ was interpreted to have a symmetric *cis*-planar trapezoidal shaped structure with the structural parameters $r_{\text{N}-\text{N}} = 2.33(12)$ Å, $r_{\text{N}-\text{O}} = 1.15(1)$ Å, $\angle \text{NNO} = 95(5)^\circ$. The long N–N bond is the weakest bond in this molecule.

The quadrupole coupling constants of the nitrogen nuclei and the dipole moment indicated that little electron rearrangement occurs on dimer formation. The spin-rotation constants of the dimer were larger than expected; this fact can be rationalized in terms of low lying electronic states. See also [23, 24].

The origin of the long N–N bond in the C_{a2v} isomer of N_2O_2 was modeled by *ab initio* valence bond calculations [25]. The very long N–N bond in this isomer is associated mostly with the nature of the hybridization and the orientation of the lone-pair atomic orbitals on each nitrogen atom. The optimum forms of the two orbitals have a large 2s component and overlap appreciably when the N–N internuclear separation is close to that of a normal single bond. The associated strong non-bonded repulsions that exist between the nitrogen lone-pair electrons lengthen the N–N bond. At N–N distances close to the equilibrium value (2.237 Å), the orbitals that form the N–N σ bond are almost entirely 2p in character and oriented at right angles to the N–O bond axes.

One of the postulated structures for the NO dimer is isoelectronic with dicyclobutane. Based on this similarity, attempts have been made to predict the stability of $(\text{NO})_2$ by computational chemistry [26].

Density functional theory and *ab initio* quantum chemistry methods were used to predict the structures and energetics of neutral and anionic N_2O_2 species [27]. When going from a neutral NO dimer to an anionic species the N–N bond lengths were pre-

dicted to decrease drastically and the corresponding N—N frequencies would increase. The relative stabilities of the different N_2O_2^- isomers suggested an ONNO structure in a *trans* configuration to be the most stable monovalent anion. The total energy of the hyponitrite ion, $\text{N}_2\text{O}_2^{2-}$, was expected to be 2.7–2.8 eV above the total energy of N_2O_2^- .

The binding energy of the NO dimer has been measured directly using velocity-mapped ion imaging [28]. The NO dimer was photodissociated to produce NO(X) and NO(A), and the NO(A) was then non-resonantly ionized to NO^+ . The threshold for the production of NO^+ ions was measured at $44893 \pm 2 \text{ cm}^{-1}$, which corresponds to a binding energy of $696 \pm 4 \text{ cm}^{-1}$.

The continuing interest in high-energy nitrogen oxides has arisen due to their potential applications as new high energy density materials (HEDM). To be useful as potential rocket propellants, metastable species must be rather high in energy relative to their more stable isomers and to potential decomposition products (e.g., $\text{NO} + \text{NO}$, $\text{N}_2 + \text{O}_2$, $\text{N} + \text{NO}_2$, or $\text{N}_2\text{O} + \text{O}$ in the case of N_2O_2). In addition to a large thermodynamic exothermicity, these species must be kinetically stable, both adiabatically (that is, relative to an energy barrier on a singlet potential energy surface) and non-adiabatically (so that decomposition via coupling to a repulsive, e.g., triplet state is unlikely). In looking for better oxidizers, several high-energy isomers of N_2O_2 were examined, with particular emphasis on the molecular structure, fundamentals of bonding and energetics relative to decomposition products [29]. The only isomer of N_2O_2 that has been characterized experimentally is the weakly bound *cis* ONNO dimer, which lies 1–2 kcal/mol lower than $\text{NO} + \text{NO}$. Figure 2 illustrates other potential structures for the N_2O_2 molecule, some with substantially higher energy than the *cis* ONNO dimer, with the calculated energy levels below each image. Five high-energy minima were located above 2NO with relative energies (in kcal/mol) indicated below each image. The four-membered ring structure (**1**) has N—O = 1.351 Å, O—O = 1.398 Å and an N—N distance essentially identical to the N=N double bond in $\text{HN}=\text{NH}$. The 1,3-diazo-2,4-dioxal[1.1.0]-bicyclobutane structure (**5**) is a minimum on

Figure 2: Potential structures and calculated energy levels for the N_2O_2 molecule. (Reproduced and modified from [29].)

the SCF potential energy surface. This C_{2v} structure possesses an N—N bond (1.322 Å) that is shorter than the N—N single bond in hydrazine (1.426 Å, H_2N-NH_2) and longer than the N=N double bond in diimide ($HN=NH$, 1.216 Å), at the same level of theory.

A tetramer of NO has been postulated and predicted by theoretical calculations, but the experimental proof is lacking. The ground-state properties of $(NO)_2$ and $(NO)_4$ have been investigated using multi-reference second-order perturbation theory (MRMP2) [30]. For the NO dimer, the MRMP2-predicted structure, binding energy (with respect to $2NO$; $D_e = 14.48 \text{ kJ/mol} = 3.46 \text{ kcal/mol}$), and dipole moment ($\mu_e = 0.169 \text{ D}$) were in excellent agreement with experimental measurements, where a range of data was shown ($D_e = 11.7\text{--}15.9 \text{ kJ/mol} = 2.8\text{--}3.8 \text{ kcal/mol}$; $\mu_e = 0.171 \text{ D}$). Probing the possibility of the presence of higher-order clusters, the stability of $(NO)_4$ was investigated and the calculation results indicated the possibility of three isomers, each resembling pairs of dimers, that were stable to dissociation to $2(NO)_2$, with the lowest-energy isomer (C_i structure) having a predicted binding energy almost identical to that of the dimer. Experimental Raman and IR data going back to 1951 were reexamined and reassigned and indicated that the best predictions of vibrational frequencies of $(NO)_2$ and $(NO)_4$ were consistent with experimental observations.

Photolysis of N_2O in an argon matrix deposited on an IR-transparent window resulted in the formation of asymmetrical N_2O_2 having the structural formula $O-O-N-N$, which has been named asymmetric dinitrogen dioxide [31]. An absorption peak at a frequency of about 1220 cm^{-1} , which falls within the region of predicted N—O stretch frequency for $asym-N_2O_2$, was present only after irradiation. See photolysis section in the chapter “Nitrous Oxide.”

IR and Raman spectroscopy are best suited as characterizing techniques for studying the $1000\text{--}2400 \text{ cm}^{-1}$ range since most N—O stretches and all but the very weak N—N stretches occur in this frequency range. Moreover, even subtle changes in molecular bonding or conformation give rise to small frequency shifts that can be detected by vibrational spectroscopy. The approximate stretching frequencies expected for N—O, N—N, and O—O bonds or different bond orders may be deduced from the data for diatomic molecules and ions. Frequencies below 1000 cm^{-1} must also be considered when a comprehensive picture of the NO and NO_2 molecular systems is desired; in fact, certain stretching frequencies, such as the ν_0 at 480 cm^{-1} in ONON and the N—N at 241 cm^{-1} in $ONNO_2$, may occur in this region. Because nitric oxide has an odd electron, its electronic ground state is $^2\Pi$, which is split about 120 cm^{-1} by spin-orbit interaction into $^2\Pi_{1/2}$ and $^2\Pi_{3/2}$ components. As a result of this small energy separation, the gas-phase IR spectrum of NO is complex [32].

4.11 Optical Properties of Nitric Oxide

The electronic and vibration spectra of nitric oxide and related nitrogen oxides are summarized here in detail because in the search for higher-energy nitrogen oxides as rocket propellants, spectroscopy is the main tool to look for elusive, short-lived species that could potentially be stabilized under suitable (e.g., cryogenic) conditions. This spectroscopy topic has been thoroughly investigated owing to the participation of NO and related oxides in atmospheric chemistry.

4.11.1 Ultraviolet Spectra of Nitric Oxide

At pressures less than 150 mm Hg the only NO absorption found down to 2200 Å was the 0–1 band of the γ system [33]. At higher pressures a strong continuous absorption setting in at about 2600 Å made observation at shorter wavelengths impossible. No discrete NO absorption was observed above 2600 Å at a pressure of 700 mm Hg, above 2500 Å at 300-mm Hg pressure, or above 2400 Å at 150-mm Hg pressure. The dimer $(\text{NO})_2$ can be detected at room temperature in compressed gaseous NO. From the temperature and pressure dependence of the UV absorption intensity (Figure 3) the enthalpy change for the reaction $2\text{NO} \rightarrow (\text{NO})_2$ and the standard enthalpy of for-

Figure 3: UV spectrum of gaseous NO and $(\text{NO})_2$ at several different pressures of NO at 298 K.

Legend: (a) baseline; (b) 1.03 atm; (c) 1.79 atm; (d) 2.54 atm; (e) 3.2 atm; (f) 4.06 atm; (g) 4.89 atm; (h) 5.72 atm; (i) 6.48 atm; (j) 7.23 atm; (k) 7.99 atm.

mation could be obtained [20]. The effective decadic molar extinction coefficient of the dimer is $E \leq 3.6 \times 10^4 \text{ mol}^{-1} \text{ cm}^{-1}$ at 199 nm.

The short-wavelength end of the UV spectrum of NO is the ionization limit. This process takes place in the upper atmosphere. Recombination of the dissociated species leads to fluorescence.

The absorption spectrum of liquid NO was also obtained through a 3-cm path length at 121 K (-152°C), with a tungsten filament as source [33]. A strong continuous absorption starting at 4000 Å and extending to shorter wavelengths and one at 5600 Å and extending to longer wavelengths were observed. Maximum transmission occurred at around 4600 Å. Since liquid NO is completely associated, the strong violet and red cut-offs are most likely due to N_2O_2 molecules.

The far UV continuum of nitric oxide was assigned to the dimer based on four points of experimental evidence [34]: **(1)** the intensity of the spectrum is proportional to $[\text{NO}]_2$; **(2)** the possibility that the carrier may be some other known oxide of nitrogen was eliminated; **(3)** from the temperature dependence the enthalpy change accompanying dissociation was 9.37 kJ/mol (2.24 kcal/mol) (100–140 K), in good agreement with 19.04 kJ/mol (2.4 kcal/mol) deduced from the dimer IR intensities; **(4)** approximate upper and lower limits to the dissociation constant, and the temperature dependence, were consistent with calculations based on the principle of corresponding states. The dissociation free energy of the dimer is 1.6 kcal/mol. The dimer continuum exhibits a maximum at 2050 Å.

The absorption spectrum of cold NO gas was photographed at high resolution between 1400 and 1250 Å for two isotopic species [35]. Resolved bands of the Rydberg series converging to vibrational levels of the $1\Sigma^+$ ground state of NO^+ revealed X bands up to $n = 15$ and ns-X bands up to $n = 11$, all of which showed a sharp rotational structure.

The $(\text{NO})_2 v_1 + v_5$ photodissociation spectrum at $3624\text{--}3629 \text{ cm}^{-1}$ proved that photodissociation arises from the dimer [36]. This photodissociation can be compared to $\text{HN}_3 + h\nu \rightarrow \text{NH} + \text{N}_2$, which is discussed in the same paper.

The dissociation barrier of $(\text{NO})_2$ was calculated to be 10.5 kJ/mol (2.5 kcal/mol). Dissociation barriers of this size would indicate that this molecule would not be long-lived. This molecule might be synthesized and stored in a solid-state matrix, but calculations indicated that the gas-phase lifetime of this molecule would be small [37].

4.11.2 Infrared Spectra of Nitric Oxide

4.11.2.1 Infrared Spectra of Gaseous Nitric Oxide

The wide-range IR spectrum of gaseous nitric oxide is shown in Figure 4.

The absorption spectrum of the “heavy” isotopic nitric oxide molecule $^{15}\text{N}^{18}\text{O}$ was studied in the IR region under high resolution [39]. Wavelength measurements and analyses of the 1-0 band at 5.58μ and the 2-0 band at 2.81μ yielded the molecular constants. The linear dependence of the spin-orbit coupling constant A upon the vibra-

Figure 4: Wide-range IR spectrum of gaseous nitric oxide. (Reproduced and modified with permission from [38])

tional quantum number ν was similar to the results for other isotopic species of the nitric oxide molecule. An overlapping impurity band at 5.43μ was identified as the 1-0 band of $^{15}\text{N}^{16}\text{O}$. The theoretical vibrational and rotational isotopic relations were verified to within observational accuracy.

The IR spectrum of gaseous nitric oxide was examined from 4000 to 1600 cm^{-1} at temperatures between 77 and 150 K with a 3.9-m and a 6-cm path length cell [40]. Features found at 1860 and 1788 cm^{-1} exhibited a quadratic pressure dependence and were assigned to the dimer $(\text{NO})_2$. The band shape of these features indicated the presence of a *cis*- $(\text{NO})_2$ isomer. The heat of formation of $(\text{NO})_2$ from monomeric NO was estimated as $\Delta H = -10.25\text{ kJ/mol}$ (-2.45 kcal/mol).

The IR spectral absorptivity of nitric oxide gas has been measured at low resolution at temperatures ranging from 300 to 1200 K , while the optical path lengths were such that the resulting data fell in the transition to strong absorbing regions [41]. The results were correlated in terms of spectral mean (or narrow band) properties as well as wide-band properties. A total IR emissivity chart for NO was constructed using the results of the band absorptance correlation. This would be of interest where NO is an intermediate in combustion processes.

FTIR spectra of NO and NO_2 are used for the analysis of NO in mixed oxides of nitrogen (MON) [42]. The absorption peaks at 1887.5 , 1900.2 , and 1912.1 cm^{-1} were selected for the calibration curve.

4.11.2.2 Infrared Spectra of Frozen Nitric Oxide

The IR spectra of frozen nitric oxide, both in the pure state and at several dilutions trapped at liquid-helium temperatures in matrices of argon or carbon dioxide, were measured in a wavenumber range from 700 and 2000 cm^{-1} (14 to $5\mu\text{m}$) [43]. NO was found as the monomer and two forms of dimer, *cis* and *trans*; the *cis* is the more stable form. Four major bands were observed, all in the region broadly assigned to the $\text{N}=\text{O}$ stretch vibrations. In a *cis* form both the symmetric and asymmetric $\text{N}=\text{O}$ stretching

modes would be IR-active but in a *trans* form only the asymmetric mode would be. The band at 1883 cm^{-1} was assigned to the nitric oxide monomer in a CO_2 matrix. The band at 1768 cm^{-1} (in solid NO or solid CO_2) was assigned to the asymmetrical vibration in the *cis* form of the dimer $(\text{NO})_2$, the band at 1862 cm^{-1} was assigned to the symmetrical vibration in the *cis* form of the dimer $(\text{NO})_2$, and the band at 1740 cm^{-1} was assigned to the asymmetrical vibration in the *trans* form of the dimer $(\text{NO})_2$.

Matrix-isolated $(\text{NO})_2$ was obtained by rapid deposition of NO/ N_2 mixtures on an optical window at 15 K, by limited diffusion of matrix-isolated NO at low temperatures, and by photochemical production of O atoms in an N_2O environment [44]. Experiments carried out using isotope-labeled ^{15}NO and N^{18}O samples indicated that *cis* and *trans* O—N—N—O and possibly another unstable *cis* form are produced.

During a near- and far-IR study of ^{14}NO — ^{14}NO and its isotopomers, ^{14}NO — ^{15}NO and ^{15}NO — ^{15}NO , isolated in an argon matrix, IR-active fundamental vibrational modes ν_1 , ν_2 , ν_3 , ν_5 , and ν_6 for each species of the dimer could be observed, as well as overtone bands $2\nu_1$ and $2\nu_5$, and combination bands $\nu_1 + \nu_5$, $\nu_1 + \nu_6$, $\nu_5 + \nu_6$, and $\nu_4 + \nu_5$ [45]. From knowledge of the 18 available frequencies of the 3 isotopic species, force constants for the *cis*-ON—NO were then calculated. The potential energy distribution calculated for each vibration showed that the ν_2 and ν_3 modes are strongly coupled and that there is no pure N—N stretching mode.

4.11.3 Raman Spectra of Nitric Oxide

The IR and Raman spectra of liquid and solid nitric oxide were measured in an attempt to prove the existence of the $(\text{NO})_2$ dimer molecule [46]. The liquid has four strong Raman lines at 1861 , 262 , 196 , and 167 cm^{-1} , two weaker Raman lines at 1760 and 487 cm^{-1} , and two strong IR bands at 1863 and 1770 cm^{-1} . Several weaker IR bands could be tentatively assigned as combinations using the observed strong IR and Raman frequencies. The spectra were found to be due exclusively to a dimer that probably exists as a bent ONNO molecule.

The Raman spectra of $(^{14}\text{NO})_2$ and $(^{15}\text{NO})_2$ and the far-IR spectra of $(^{14}\text{NO})_2$ at 20 K were measured in order to identify the bond strengths of the dimer [47]. The band wavenumbers were assigned on the basis of a C_{2v} molecular model, and normal coordinate calculations were performed for a variety of assignments. The vibrational mode assignment that yielded the best fit was selected for further study.

Infrared and Raman spectra of polycrystalline samples of dimeric nitric oxide N_2O_2 were measured between 18 and 80 K, and several new low-frequency peaks could be observed [48]. The Raman spectrum of the liquid at 115 K was measured in an attempt to distinguish between vibration characteristics of the dimerized molecule and of the lattice.

4.12 Magnetic Properties of Nitric Oxide

Using a specially designed cryostat, the magnetic susceptibility of liquid nitric oxide was measured by both the Faraday method and the Gouy method [49]. A temperature variation of susceptibility was found corresponding to an equilibrium dissociation of feebly magnetic dimer molecules into paramagnetic monomers. Measurements of the susceptibility of liquid nitric oxide-liquid krypton mixtures were used to estimate the contribution of the $(\text{NO})_2$ molecule, which was found to be about 0.026×10^{-2} per mol of $(\text{NO})_2$. The degree of dissociation of liquid nitric oxide varied from 2.7% at 110 K to 5% at 120 K and the heat of dissociation of the dimer was found to be $15.52 \pm 0.62 \text{ kJ/mol}$ ($3710 \pm 150 \text{ cal/mol}$).

4.13 Solubility of Nitric Oxide

The solubility of NO in N_2O_4 is due to the formation of N_2O_3 . The two (three) nitrogen oxides are miscible over the entire range of compositions.

The solubility of NO in water and blood is a key property for the biological activity of this compound in nerve signal transmission and blood pressure regulation.

In all cases where the solubility of NO is investigated, one must take precautions to avoid contact with air or dissolved oxygen, which might cause the formation of NO_2 and disturb the solubility measurements.

5 Chemical Properties of Nitric Oxide

5.1 Autoxidation of Nitric Oxide

The most prominent property of nitric oxide is its autoxidation as soon as it comes into contact with air. This reaction has been the key to the historical Birkeland process for industrial production of nitric acid from air by passing air through an electric arc discharge. For a long time, this process has been a major source of urgently needed fertilizer to increase agricultural production and feed the hungry among the world's increasing population, until the Haber-Bosch process made ammonia the prevalent method of atmospheric nitrogen fixation for fertilizers. Ammonia can be used as a fertilizer or converted to nitric oxide, nitrogen dioxide, and nitric acid by air-oxidation over a platinum catalyst.

We were not quite sure whether the heading of the current section should be "Autoxidation" or just plain "Oxidation," but we decided that "Autoxidation" better described this property of nitric oxide. The autoxidation of nitric oxide plays an important role in atmospheric air pollution. Consequently, the majority of published studies describing the autoxidation of nitric oxide were done in connection with and support

of air pollution research. Considerable effort has been devoted to the removal of nitric oxide from combustion products in stationary or mobile power plants before it has a chance to escape to the atmosphere and oxidize itself to nitrogen dioxide. NO and NO_x removal from combustion products can be done by reduction or decomposition or oxidation and wet absorption in a scrubber.

Pressurant gases vented from MON storage and propellant transfer containers contain varying amounts of NO, which must be oxidized to NO₂ before they can be washed out in a scrubber before the pressurant gases can be vented to the atmosphere. In designing NO_x scrubbers at launch facilities, the rate of autoxidation of NO in the presence of additional air provided must be known.

Dinitrogen tetroxide and nitric acid and their mixtures are important storable rocket propellant oxidizers. All nitrogen in those two oxidizers has at one point or another gone through the intermediate stage of nitric oxide. This is why nitric oxide reactions are of importance for rocket propellants.

5.1.1 Kinetics of Nitric Oxide Autoxidation

The autoxidation reaction of NO takes place in polluted atmospheres and is instrumental in the formation of smog. It is also a key step in the industrial production of NO₂, N₂O₄, and HNO₃.

The thermal oxidation of nitric oxide at very low concentrations in the parts-per-million range has been investigated under simulated atmospheric conditions by long-path IR spectrophotometry [50]. At 293 K (20 °C), the reaction followed pseudo second-order kinetics with a rate constant of $(2.0 \pm 0.1) \times 10^{41.2} \text{ mol}^{-2} \text{ s}^{-1}$, defined by

$$k = -d[\text{NO}]/dt = K[\text{NO}]^2[\text{O}_2].$$

Excess water vapor and the presence of different surfaces had no apparent effect on the order or the rate constant. Removal of nitrogen dioxide from the gas phase was attributed largely to adsorption on silicon monoxide and chromium-plated surfaces. The rate of adsorption is increased by the presence of nitric oxide and water vapor in the gas phase.

The reaction between molecular oxygen and two nitric oxide(II) molecules was modeled with high-level *ab initio* wave function computational chemistry methods, including geometry optimizations with coupled cluster and complete active space with second-order perturbation theory levels [51]. The best calculated estimate of the activation energy of this reaction was 6.47 kJ/mol.

5.1.2 Reaction of Nitric Oxide with Nitrogen Dioxide

Dinitrogen trioxide, the most important ingredient of MON, is made by the reaction of nitric oxide with nitrogen dioxide

and MON is a mixture of dinitrogen trioxide and dinitrogen tetroxide. MON is an important rocket propellant oxidizer, which is why the reaction between NO_2 and NO should be discussed here in a book on rocket propellants. It is important that MON chemical composition should not change when it is transferred from one container to another while loading a spacecraft with propellants or while pressurizing and depressurizing a propellant tank. However, the foregoing reaction is an equilibrium and the reverse reaction,

the dissociation of dinitrogen trioxide into its constituents, is just as likely to occur at higher temperatures. Each time a pressurized MON tank is vented, it preferentially loses some of the NO and the composition of the liquid phase shifts. If MON lost all its NO and N_2O_3 , the remaining oxidizer would be more corrosive and become capable of stress corrosion of titanium and stainless-steel tanks.

The gas-phase reaction of nitric oxide with nitrogen dioxide occurs on a global scale in the upper atmosphere, although only a trace of dinitrogen trioxide can be detected at any moment because dinitrogen trioxide exists mostly in the liquid state and not in the vapor state.

The liquid-phase reaction of nitric oxide with nitrogen dioxide (or dinitrogen tetroxide) is important to rocket propellant chemists who are about to make MON usable as a rocket propellant.

The section on absorption spectra of N_2O_3 (the chapter “Dinitrogen Trioxide”) contains more information on the reaction of nitric oxide with nitrogen dioxide and the dissociation of dinitrogen trioxide.

5.1.3 Reaction of Nitric Oxide with Ozone

The rate of reaction between nitric oxide and ozone that occurs in the ozonosphere was followed optically at 230 and 198 K (-43 and -75°C) [52]. The reaction appeared to be elementary bimolecular

and the rate constant was $k = 0.8 \times 10^{12} e^{-2500/RT} \text{ mol}^{-1} \text{ s}^{-1}$. The preexponential factor for this reaction was compared with those of six other elementary gas-phase reactions of the type

involving the oxides of nitrogen for which the energies of activation were higher. For this series of similar reactions the molecular complexity of the reactants was about constant (five or six atoms), and there appeared to be no systematic difference in pre-exponential factor between the fast and slow reactions.

5.2 Combustion Sustained by Nitric Oxide as an Oxidizer

An attempt was made to use liquid nitric oxide as an oxidizer with non-hypergolic fuels such as kerosene JP-4 and methanol, but the poor reactivity required a very long $L^*38.4\text{ m}$ (!) engine and very long dwell times in the reaction chamber [53, 54]. It was impossible to achieve ignition with JP-4, and with methanol the engine sputtered.

5.3 Analysis of Nitric Oxide

Analytical methods are needed to determine the concentration of NO (or N_2O_3) in mixed oxides of nitrogen and in ambient air.

Nitric oxide concentration in air can be determined using a chemiluminescent reaction involving ozone: A gas sample containing nitric oxide is mixed with an excess of ozone in air. The nitric oxide reacts with the ozone to produce oxygen and nitrogen dioxide. This reaction also produces light (chemiluminescence), which can be measured with a photodetector. The amount of light produced is proportional to the amount of nitric oxide in the sample.

Other methods of analysis include electroanalysis (amperometric approach), where NO reacts with an electrode to induce a current or voltage change.

5.4 Decomposition and Thermal Stability of Nitric Oxide

Under the conditions of an electric discharge in air, nitric oxide decomposes just as fast as it forms. Only if the heated air is rapidly quenched can useful amounts of nitric oxide be obtained, as was once done on a commercial scale in the Birkeland process for making nitric acid from air.

The standard enthalpy of formation of gaseous nitric oxide is $+90.29\text{ kJ/mol}$. Note that the enthalpy of formation is positive, similar to that of nitrous oxide or other monopropellants. The decomposition of NO for removal from combustion products can be achieved thermally and/or by contact with a catalyst, preferably in the presence of a reducing gas like ammonia or hydrazine. This is the basis of industrial denox flue gas denitrification processes, also called selective catalytic reduction. The kinetics of NO and NO_x removal reactions have been investigated thoroughly and would fill a book by themselves. They have little relationship to reactions in rocket engines and are not discussed any further in this text.

5.4.1 Thermal Decomposition of Nitric Oxide

The effects of nitrogen and oxygen on the kinetics of decomposition of nitric oxide have been investigated [55]. In the temperature region in which the heterogeneous mechanism prevails (at $T < 1000$ K), the presence of nitrogen has a marked retarding influence on the reaction rate of nitric oxide due to poisoning of the surface. On the other hand, the addition of oxygen results in a marked increase in the rate of decomposition of nitric oxide over the entire temperature range studied. At high concentrations of oxygen the following empirical rate expression obtains:

$$-d[\text{NO}]/dt = k_a[\text{NO}]^2 + k_b[\text{NO}][\text{O}_2]^{1/2}$$

with an activation energy of 327 kJ/mol (78.2 kcal/mol) for the rate-determining step. The decomposition of nitric oxide is autocatalytic. On the basis of these experimental observations, a mechanism was proposed involving a chain reaction propagated by the atomic species formed in the reaction.

The thermal decomposition of pure nitric oxide and of mixtures with nitrogen or helium was studied in quartz vessels at 1170 to 1530 K [56]. Above about 1400 K, the reaction was homogeneous and cleanly second order in NO throughout the course of decomposition. A change in the surface-to-volume ratio left the rate unchanged, as did the addition of a fourfold excess of nitrogen or helium as a diluent. Above 1400 K, the activation energy was constant at 63.8 ± 0.6 kcal/mol.

The nitrogen oxide equilibrium was recalculated on the basis of the new spectroscopic value for the dissociation energy of dinitrogen [57]. Complete tables of the equilibrium composition were given in the temperature range up to 5000 K. The maximum amount of fixed nitrogen (at 1 atmosphere pressure and a nitrogen oxygen ratio as in natural air) is around 5 mol percent and occurs at a temperature of around 3500 K.

The decomposition of nitric oxide in a shock wave was studied in a shock tube in which the NO concentration was followed as a function of time behind the shock front by absorption of 1270 Å radiation, where ground vibrational states of reaction products O_2 and N_2 are essentially transparent [58]. The absorption coefficients of the species NO, O_2 , and N_2 as functions of the respective vibrational temperatures were determined by measuring the absorption by the shock-heated gas at a point in the time history corresponding to complete vibrational relaxation but before the onset of dissociation. Time history analyses were conducted on a total of 42 shock-tube runs covering a temperature range of 3000–8000 K on six mixtures of NO and air with argon.

Mixtures of NO in argon (0.01–5.0%) and NO with H_2 in argon (1% NO, 1% H_2) were passed through a ceramic flow tube reactor at temperatures between 1500 and 2100 K at atmospheric pressure [59]. A portion of the NO decomposed during its passage through the reactor. The fraction of initial NO leaving the reactor was monitored as a function of flow rate (or equivalently as a function of residence time in the reactor). The reactor temperature and gas composition were varied as experimental parameters. Five mixtures were used: 5% NO, 1% NO, 0.1% NO, 0.01% NO, and 1% NO/1% H_2 ,

all in a balance of argon. Theoretical models were developed for the chemically reacting flow and used to determine the rate constant values by parametric optimization. The rate constant for $\text{NO} + \text{O} \rightarrow \text{N} + \text{O}_2$ was found to be

$$k_2 = 1.72 \times 10^{9 \pm 0.1} T \exp(-38.64/RT)$$

in a temperature range between 1750 and 2100 K, and the rate constant for $\text{NO} + \text{H} \rightarrow \text{N} + \text{OH}$ was found to be

$$k_{10} = 1.74 \times 10^{14 \pm 0.2} \exp(-49.20/RT)$$

in a temperature range between 1750 and 2040 K. These results compared well with those of previous workers and were incorporated into least-squares curve fit analyses to yield rate constant expressions useful over a wide temperature range for both reactions.

5.4.2 Catalytic Decomposition of Nitric Oxide

It would be of interest to compare the decomposition of nitric oxide and nitrous oxide side by side in the same apparatus and with the same catalysts. If a small percentage of nitric oxide in nitrous oxide lowered the temperature above which the catalytic decomposition of nitrous oxide as a monopropellant becomes self-sustaining, this might expand the range of applications where nitrous oxide monopropellants can be used without having to preheat the catalyst. The same $\text{NO}/\text{N}_2\text{O}$ mixture could also be used as an oxidizer in hybrid or bipropellant engines.

A series of catalysts composed of barium oxide supported on magnesium oxide with Ba loadings up to 7 mol% has been studied for NO and N_2O decomposition [60]. Nitrous oxide is an intermediate in the decomposition of nitric oxide. With this particular catalyst, the rate of N_2O decomposition was much faster than that of NO decomposition. The ratio of activities may reverse for other catalysts. But it is not only the rate of decomposition but also the onset of exothermicity that would determine if NO addition to N_2O is helpful to speed up its decomposition or not.

5.4.3 Photolysis of Nitric Oxide

Nitric oxide is both formed from air and decomposed by intense UV radiation in the upper atmosphere and plays a key role in atmospheric chemistry, air pollution, and ozone destruction. The photolysis of nitric oxide and the recombination of N and O atoms are important chemical reactions in the Earth's atmosphere. Photolysis of NO and quenching of excited states may lead to more energetic oxidizers.

Electronically excited $\text{NO}(A^2\Sigma)$ was produced by irradiation with the 2144- and 2265-Å lines of a cadmium arc at NO pressures from 2.67 to 80 kPa (20 to 600 mm Hg) [61]. The products were nitrogen and nitrogen dioxide. A pressure drop accompanied the reaction equivalent to the nitrogen produced. The quantum yield of nitrogen formation was independent of irradiation time and incident intensity. These results,

when combined with radiative lifetime measurements, showed that removal of $\text{NO}(A^2\Sigma)$ occurred on nearly every collision.

At an even shorter wavelength of UV, NO was photolyzed at 1550–1650 Å using a hydrogen discharge and at 1470 and 1236 Å using xenon and krypton discharges, respectively [62]. The products at all wavelengths were N_2 and NO_2 . At 1470 Å small amounts of N_2O were detected. The quantum yield of N_2 increased over the nitric oxide pressure range 0.67–120 kPa (5–900 mm Hg) from around 0.2 to 0.5 and also with added inert gas. Quantum yields of NO_2 production and of NO decomposition increased in a similar manner, and the wavelength had no profound effect. Since 1236-Å light ionized NO, it was concluded that the recombination of NO^+ and an electron would lead to an excited molecule that decomposed, as it does at 1600 and at 1470 Å, into N and O atoms. These atoms reacted with excess NO, producing N_2 and NO_2 .

Photodissociation of NO in the middle and upper atmosphere was examined using a line-by-line approach to describe competitive absorption in the NO δ bands and O_2 Schumann-Runge bands [63]. A new analysis of O_2 absorption resulted in greater transmission of UV radiation in the Schumann-Runge (5–0) band in comparison with previous studies, leading to increased rates for photolysis of NO in the $\delta(0-0)$ band. Absorption in strong lines of the NO δ bands was shown to make a non-negligible contribution to atmospheric opacity at wavelengths that are important for NO photodissociation. Depending on variations in solar irradiance, photolysis rates at altitudes below 100 km may be smaller during a solar maximum compared to a solar minimum. Thus one must consider the effects of varying opacity by NO in the atmosphere.

Nitrous oxide, N_2O , is a natural source of stratospheric NO, where NO is formed by the photolysis of N_2O [64].

5.4.4 Microwave-Assisted Decomposition of Nitric Oxide

The decomposition of NO by a continuous or pulsed electrodeless microwave plasma discharge of NO/He or NO/Ar mixtures was studied at NO and rare-gas flow rates of 2–50 and 1000 standard cm^3/min , respectively [65]. Although a stable discharge could be maintained in a low total-pressure range of 0.13–46 kPa (1–350 mm Hg) for NO/He mixtures, stable microwave discharge could be maintained in the wide total-pressure range of 0.13–101 kPa (1–760 mm Hg) for NO/Ar mixtures at a microwave power of 200 W. The decomposition efficiency of NO was measured as a function of the microwave power and the NO flow rate in a continuous mode. Emission spectroscopic data gave information on the decomposition mechanism of NO in He and Ar discharges.

5.5 Detonability of Nitric Oxide

5.5.1 Detonability of Liquid Nitric Oxide

Nitric oxide is the simplest known molecule capable of detonation, detonating in all three phases.

At the former NASA Lewis Research Center, controlled nitric oxide decomposition in a reactor was once considered to generate hot air for high-speed supersonic wind tunnel tests, as a means of providing additional enthalpy to a heated air stream to achieve temperatures associated with flows at Mach numbers in a range of 8 to 9 [66]. The practice of storing NO in the liquid state was discontinued after one of the storage tanks with liquid NO exploded. Since storing and pumping liquid NO was preferred to handling it in the gas phase, it became necessary to characterize the detonability of NO in all three phases.

Potentially catastrophic explosions propagated in condensed-phase NO at temperatures near its normal boiling point during controlled detonation experiments [67]. At 101 and 303 kPa (1 and 3 atm) initial pressure, brisant (shattering) detonations occurred with velocities exceeding 5000 m/s and estimated peak pressures as high as 10 GPa (100000 atm). At an initial pressure of 2.32 MPa (23 atm), a less catastrophic explosion severely oxidized stainless steel and produced momentary pressure pulses estimated at 202 MPa (2000 atm). Propagation of the brisant detonations seemed to be associated with the presence of gas bubbles, either from NO vapor or from N₂ impurity. All explosion experiments were in vertical CRES 304 stainless-steel pipe, 52 mm i. d., 4 mm wall thickness, and 1220 mm length. All samples were initiated by the detonation of a 135-g RDX booster charge. A control experiment, done in the same way using liquid N₂O at 85 K, showed no evidence of oxidation or explosion. The RDX compressed solid booster charge was separated from the interior of the pipe by a sealed aluminum diaphragm. The initiation train was an Army Engineers-type electric detonator and a 22-g pellet of tetryl. The progress of explosions up the pipe was sensed by detectors shorting five horizontal pairs of parallel stainless-steel platelets inside the pipe positioned 76, 149, 294, 586, and 1168 mm above the diaphragm. A Cathode Ray Tube (CRT) oscillograph recorded the shorting events against time, to within 1 μs accuracy, as pulses on a raster display. Each station in the pipe was uniquely identified by pulse shape. Three copper-constantan thermocouples, each inside a coil of stainless-steel small-diameter tubing, were positioned inside the pipe above the 76-, 586-, and 1168-mm stations. Thermocouple data were read from a calibrated self-balancing indicating potentiometer using a reference junction in boiling nitrogen. The shorting sensors and thermocouples were held inside the pipe by stainless-steel plugs screwed into bosses leading through the pipe and cooling jacket.

Liquid nitric oxide has been distilled for a number of years to alter the ¹⁵N/¹⁴N isotope ratio in the production of ¹⁵N-labeled chemicals. An NO distillation system had been operated at Los Alamos National Lab (LANL) since 1963 with distillation units containing up to 40 kg of NO. An explosion occurred in January 1975 which involved

an estimated 50 g NO in one of the product collection traps. During the subsequent investigation, it was found that liquid NO is an extremely sensitive explosive [68]. The detonation velocity for the liquid at 115 K was estimated to be 5.62 ± 0.07 mm/ μ s and the detonation pressure as 100 kbar. The failure diameter for the liquid confined in stainless steel was between 4.6 and 3.1 mm. A high-pressure reaction, but not a detonation wave, propagated through a tube as narrow as 0.7 mm. At LANL, the failure diameter was determined by detonating the liquid in an assembly containing a series of stainless-steel tubes with the diameter decreasing in steps. Each section was either ten diameters long or 100 mm long, whichever was longer. The booster consisted of an SE-1 detonator, a 12.7-mm-long tetryl pellet and a 25-mm-diameter $\times$ 25-mm-long PBX-9404 charge with a 2.5-mm-thick stainless-steel barrier. In the first shot the inside diameters were 22.1, 18.9, 15.8, 12.6, 9.4, 6.2, 4.6, and 3.1 mm with a 1.65-mm wall thickness. No fragments were recovered from this assembly. The inside diameters in the second shot were 6.2, 4.6, 3.1, 1.6, 0.71, and 0.25 mm with wall thicknesses of 1.65, 1.65, 1.65, 0.25, 0.113, and 0.13 mm, respectively. The entire length of the 3.1-mm-diameter tube was recovered, but no fragments of the 4.6-mm-diameter tube were found. The 0.7-mm-diameter tube was ruptured.

A bullet impact sensitivity test of liquid NO showed that a violent reaction occurred in a 1.6-mm wall thickness, 76-mm outer diameter (OD) stainless-steel tube, 254 mm long filled to a depth of 100 mm with liquid NO when it was struck by a .30-cal bullet weighing 5.8 g and traveling at 451 m/s [69]. In a similar test no reaction occurred with nitromethane.

Liquid nitric oxide boiling at 121 K in a 406-mm-long steel pipe with a 26.64-mm inner diameter (ID) and 3.38-mm wall thickness, open to the atmosphere at the top and closed at the bottom with a 0.08-mm-thick Teflon membrane, when boosted with a 50-g tetryl donor, and with only the 0.08-mm Teflon as a gap, detonated at high velocity. High-velocity detonations were also obtained with attenuated shocks at 102- and 254-mm gap thicknesses. The average detonation rate of boiling NO was 5400 m/s [70]. Similar tests were conducted with non-boiling NO. See also [71–73].

Measurements of detonations of homogeneous liquid nitric oxide initially at $T = 119$ K and $\rho_0 = 1.28$ g/cm³ using plane-shock initiation in mirror-covered wedges demonstrated a detonation in preshocked material (superdetonation) that overtook the smooth input shock [74]. Its transverse irregularities continued in the unsupported detonation. The input shock ran approximately 3 mm at $u_1 = 3.8 \pm 0.2$ km/s. Behind it the fluid had $u_p = 0.89 \pm 0.02$ km/s, $p = 4.3 \pm 0.03$ GPa, and $\rho = 1.67 \pm 0.03$ g/cm³, and the superdetonation had $D^* \approx 6.9$ km/s. In 356-mm-long graphite tubes with a 25.4-mm ID, measured detonation velocity was $D = 5552 \pm 3$ m/s. Failure diameter in graphite was below 8 mm. Free-surface velocities of 1- and 2-mm aluminum flyer plates terminating the detonation axis were near 1.5 km/s approximately as predicted for Chapman-Jouguet (C-J) flow at $D_\infty = 5564$ m/s, $u_p = 1.34$ km/s impinging on aluminum.

In August 2004, the US Chemical Safety and Hazard Investigation Board (CSB) issued a case study examining the causes of a September 2003 nitric oxide leak and explosion that had occurred at a Sigma-Aldrich Corporation-owned Isotec facility, an ^{15}N isotope separation plant in Miami Township, Ohio, near Dayton [75]. The accident destroyed a 91-m (300-ft.)-tall nitric oxide distillation column, installed below ground. The explosion caused a 6-m (20-ft.)-diameter, 2.4-m (8-ft.)-deep crater and structural damage (Figure 5). If the column had been mounted above ground, the damage would have been much more severe.

Figure 5: Post-accident scene at Isotec ^{15}N isotope separation plant after explosion of nitric oxide. (From CSB case study.)

The explosion happened as company operators worked to shut down the system after a nitric oxide leak and empty the liquid NO . A large steel panel from a blast containment structure was blown off, striking a 23-metric-ton (52000-lb) carbon monoxide storage vessel. Leaking CO gas ignited and burned for more than an hour. The blast destroyed other nearby plant structures and blew out windows in the main office building about 42 m (140 ft.) from the explosion. Glass shards lacerated the hand of one employee, but no other people were injured. Small chunks of concrete and metal shards were propelled as far as 300 m (1000 ft.) and fell on adjacent property. The extensive destruction of the distillation system prevented identification of the exact cause of the nitric oxide leak and type of stimulus that triggered the explosion. The study concluded that the most likely cause was a hole that had developed somewhere along the more than 670 m (2200 ft.) of pipe in the distillation column, releasing nitric oxide liquid into the surrounding vacuum jacket. The CSB study revealed that Isotec had experienced two earlier incidents in similar distillation columns in 1995 and 1998.

Both involved piping failures that allowed nitric oxide to leak into the vacuum jacket. One involved a small explosion below ground, but no corrective action was taken in time to prevent the third, more severe, incident.

5.5.2 Detonability of Gaseous Nitric Oxide

An attempt was made at predicting the detonability of gases from theoretical considerations, and the reliability of predictions was tested against experimental data for nitric oxide or ozone. It was predicted that ozone would detonate but nitric oxide would not [76].

The method gives the length of the reaction zone, and a governing equation was obtained by combining the Rayleigh line equation, the Hugoniot equation, and reaction rate equations.

At the US Bureau of Mines, the detonability of nitric oxide was tested in the gaseous state and in the solid state (see below) [70]. Detonability experiments with gaseous NO at ambient temperature were conducted at ambient pressure (0.1 MPa) and at elevated pressures of 2.17, 2.9, and 7 MPa. Experiments at 0.1 MPa initial pressure were conducted in a closed steel vessel 178 mm in diameter and 3.66 m long. The explosive charge, together with a No. 6 electric blasting cap, was suspended at one end of the vessel, which was then evacuated and filled with NO. Propagation rates were measured at the downstream end of the vessel with pressure-sensitive switches spaced 500 mm apart. For initiators weighing 43 g or less, reaction velocities on the order of 1000 m/s were observed, but velocities in excess of 2000 m/s were observed for initiators weighing 60 g or more. The high-velocity reactions were described as detonations in the true sense, while the lower-velocity reactions were presumably unstable and were referred to as deflagrations. Initiation studies with gaseous NO were extended to 2.17 and 2.90 MPa using 82.6-mm-ID $\times$ 1.22-m-long closed steel pipes. At 2.17 MPa, the initiating charge weight corresponding to the deflagration/detonation threshold was between 2 and 20 g of pentaerythritol tetranitrate (PETN); at 2.90 MPa, the critical charge weight was between 1 and 2 g. At 7 MPa, a small detonator containing only 0.9 g PETN was sufficient to initiate a detonation that propagated at a rate of 2100 m/s.

5.5.3 Detonability of Solid Nitric Oxide

In tests at the US Bureau of Mines with frozen nitric oxide at 78 K with a charge length of 510 mm and 26.64-mm ID $\times$ 3.38-mm-wall steel pipe all samples detonated at high order with a detonation velocity of 6000 m/s when initiated by a 50-g tetryl booster [70].

Samples of solid nitric oxide (NO) weighing up to several hundred milligrams at 30 K have been shocked by detonating PETN boosters in a high-vacuum chamber [77, 78]. The products expanding from the shocked sample were identified, and the product concentrations were measured as a function of time by quadrupole mass spec-

trometry. The gases expanding from unconfined shocked solid NO contained mostly NO_2 , N_2O , and unreacted NO. Nitrogen and oxygen, the expected equilibrium products from detonating NO, were seen in somewhat smaller amounts. Confined samples gave a greater proportion of N_2 and O_2 . The products observed were similar in many respects to those obtained from NO compressed to very high pressures in a diamond anvil cell and those collected from NO shocked in a closed container.

6 Toxicity and Physiological Effects of Nitric Oxide

With nitric oxide rapidly converting to nitrogen dioxide once released into air and inhaled, the inhalation toxicity of nitric oxide would essentially be the same as that of nitrogen dioxide. During its short life span before it becomes oxidizer, nitric oxide may have clinical applications when administered by inhalation and cause selective rapid pulmonary vasodilatation in emergency cases of pulmonary hypertension. It is a selective pulmonary vasodilator effective in the management of persistent pulmonary hypertension of newborns. Inhalation of NO with air is accompanied by inevitable conversion to NO_2 [79].

Knowing that nitric oxide is very reactive, it was a surprise when it was discovered that it is a ubiquitous bioactive molecule and plays a key role in nerve signal conduction and excitement, including processes that are stimulated by sildenafil (Viagra) or similar drugs. The vasodilatory effect of NO plays a role in the achievement and maintenance of erection. Vasodilation of blood vessels supplying the *corpus cavernosum* results in more blood flowing in and, hence, erection. This is the mechanism of sildenafil (Viagra). Nitric oxide can occupy ligand positions in transition metal-hemoglobin, such as ferric and ferrous hemoproteins, similar to those occupied by oxygen or carbon monoxide. The bright red color of meat preserved with sodium nitrite-containing pickling salt can be attributed to such complexes. Food safety agencies limit the amount of nitrite allowed in pickling salt because it can lead to carcinogenic *N*-nitrosamines in the food.

Nitric oxide is biosynthesized endogenously from L-arginine, oxygen, and nicotinamide adenine dinucleotide phosphate (NADPH) by various nitric oxide synthase enzymes in the blood. Nitric oxide synthases are a family of enzymes catalyzing the production of nitric oxide from L-arginine. NO is an important cellular signaling molecule. It helps modulate vascular tone, insulin secretion, airway tone, and peristalsis and is involved in angiogenesis and neural development. Nitric oxide also serves as a neurotransmitter between nerve cells.

Nitric oxide takes part in the lowering of blood pressure following the administration of alkyl nitrites or alkyl nitrates and acts on the cardiac muscle to decrease contractility and heart rate.

Nitric oxide diffuses rapidly and isotropically through most tissues with little reaction but cannot be transported through the vasculature due to rapid destruction by

oxyhemoglobin. The rapid diffusion of nitric oxide between cells allows it to locally integrate the responses of blood vessels to turbulence, modulate synaptic plasticity in neurons, and control the oscillatory behavior of neuronal networks. Nitric oxide is not necessarily short lived and is intrinsically no more reactive than oxygen. The reactivity of nitric oxide *per se* has been greatly overestimated *in vitro* because no drain is provided to remove the nitric oxide. Nitric oxide persists in solution for several minutes in micromolar concentrations before reacting with oxygen to form much stronger oxidants like nitrogen dioxide. Nitric oxide is removed within seconds *in vivo* by reaction with oxyhemoglobin. The direct toxicity of nitric oxide is modest but is greatly enhanced by reacting with superoxide to form peroxynitrite (ONOO^-). Nitric oxide is the only biological molecule produced in high enough concentrations to outcompete superoxide dismutase for superoxide. Nitric oxide may be a mediator for inflammation. Nitric oxide will form nitrosamines with many amines. Nitrosamines are known carcinogens.

7 Applications of Nitric Oxide

As far as rocket propellants are concerned, the main application of nitric oxide is in the preparation of MON by bubbling it into N_2O_4 to make an $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$ mixture that minimizes stress corrosion in titanium alloy tanks. There is no military specification for the procurement of NO, and contaminants in NO must be carefully controlled to prevent contamination of the MON produced. When the US Air Force (USAF) announced a procurement of NO in 2007, the requirement was as follows:

The Defense Energy Support Center (DESC) intends to procure on a full and open competition basis for 279 pounds of Nitric Oxide (NO), NSN 9135-01-0146-5135, with a minimum purity of 99.5% by weight. The NO product provided will conform to producer's specifications, standards and quality assurance practices and be the same NO product offered for sale in the commercial marketplace.

No specification was given as to what the remaining 0.5% were allowed to contain. There was an incident where NO was contaminated by SO_2 and nitrosyl sulfuric acid (remember the lead chamber process?) precipitated and clogged some flow passages. The problem may have arisen at a filling plant where both SO_2 cylinders and NO cylinders shared the same Compressed Gas Association (CGA) connection, CGA 660, and cross-contamination or shared cylinder use for both gases is possible.

Other applications of NO are in isotope separation for the production of $^{15}\text{N}_2$ and, to a very limited extent, use as an airway dilatant to treat acute cases of respiratory failure.

Nitroaliphatic Compounds

1 Nitroaliphatic Compounds (Nitroalkanes)

The topic of nitro compounds had to be distributed over four chapters because it would have been a very large chapter that would have made it more difficult for readers to find information on a specific compound, and it would also have been difficult to arrange 30 chapters among five sub-volumes such that each sub-volume is about the same size. That arrangement was made easier by dealing with smaller chapter increments.

The chapter at hand, dealing with higher nitroaliphatic compounds, is the continuation of the chapter “Nitromethanes” that had to be separated and moved to its own chapter in order to facilitate an even distribution of chapters between the five sub-volumes that constitute the *Encyclopedia of Oxidizers*. The chapter “Nitromethanes” contains introductory information on the production of all nitroalkanes and contains several tables in which the properties of nitromethanes are compared to the properties of higher nitroalkanes. Therefore, if the reader does not find the desired information in the current chapter on higher nitroaliphatic compounds, it is recommended to open the chapter “Nitromethanes” and search there.

Besides nitroalkanes with more than one carbon atom, the most important aspects of the chapter at hand are nitro compounds that carry other substituents in addition to a nitro group or in addition to several nitro groups on the carbon skeleton.

2 Nitroethane

Nitroethane, $C_2H_5NO_2$, CAS RN [79-24-3] is often added to nitromethane to render it less sensitive. It is a by-product of nitromethane production. It is unlikely to be used as a monopropellant because it is so under-oxidized, with an oxygen balance of only –95.9%. However, mixtures of nitroethane with nitromethane or tetranitromethane would potentially make a more energetic propellant (if not an explosive, depending on what you want). It is (was) widely used as a solvent for coatings and paints (nitro lacquer). It may also be used as an additive to diesel fuel to improve the cetane number.

2.1 Production of Nitroethane

The four lower mononitroparaffins (nitromethane, nitroethane, 1-nitropropane, and 2-nitropropane) are made on a large scale by oxidizing an excess of vapor-phase propane with nitric acid within a temperature range of 370–450 °C and pressure of 8–12 atmospheres. This reactant combination sounds more like a rocket propellant combination and accidental explosions can indeed occur during the process. Approx-

imately 40% of the nitric acid is converted to nitroparaffins; the remainder acts as an oxidizing agent to produce unwanted oxygenated by-products and is reduced to nitric oxide. The typical product composition is 48.2 mol-% 2-nitropropane, 22.0 mol-% nitromethane, 16.6 mol-% nitroethane, and 13.2 mol-% 1-nitropropane. Industrial grades of nitroethane contain these by-products as contaminants.

2.2 Physical Properties of Nitroethane

Several of the physical properties of nitroethane have already been included in the preceding tables, where the properties of nitromethane and nitroethane and other nitroalkanes were compared by listing them in the same table next to each other. The physical properties of nitroethane are summarized in Table 1.

Table 1: Physical properties of nitroethane.

Property	SI units	Other units			References
Molecular mass	75.07 g/mol				
Freezing point	223 K	−50 °C			[1]
Boiling point	387 K	114 °C	237 °F		[2]

Enthalpy of formation	−143.9 kJ/mol	−1917.4 kJ/kg	−34.4 kcal/mol	−458.3 cal/g	[2]
ΔH_{298}^f	−143.9 kJ/mol		−34.4 kcal/mol		[4]

The vapor pressure of nitroethane as a function of temperature was already listed in chapter “Nitromethanes” in the nitroalkane section. See also [5–7].

2.2.1 Thermodynamic Properties of Nitroethane

The enthalpies of formation of ethane and propane nitro derivatives were obtained for both the standard state and the gas phase based on experimental results and published data from other sources as tabulated in Table 2 from reference [8]. The bond dissociation energies of the ethane and propane nitro derivatives were calculated using the enthalpies of atomization and the energies of non-valent interactions of nitro

Table 2: Thermochemical characteristics of ethane and propane nitro derivatives

Compound	Physical state	Standard enthalpy of formation ΔH_f^{298}		Enthalpy of evaporation ΔH_{evap} at 298k		Vapor state enthalpy of formation ΔH_f^{298} (G)

Data source: [8]

groups, and the calculated values were compared with the kinetic data on thermal decomposition.

Based on a heat of combustion of 326.6 ± 0.3 kcal/mol determined calorimetrically, a standard heat of formation of -135 kJ/mol (-32.3 ± 0.3 kcal/mol) has been calculated for liquid nitroethane and of -96 kJ/mol (-22.9 kcal/mol) for nitroethane vapor [9]. The freezing point of nitroethane is 183.69 K and the heat of fusion is 9.85 kJ/mol (2.355 kcal/mol) [10].

2.2.2 Molecular Structure of Nitroethane

The dissociation energies of the bonds in polynitroethanes were determined from the energies of the non-valence interactions of nitro groups with each other and compared to the available thermodynamic and kinetic data [11]. The energies of the non-functional interaction of nitro groups were used to calculate the dissociation energies of bonds in nitroethyl radicals. The dissociation energy of the C–NO₂ bond in the nitroethane molecule calculated with the use of the enthalpies of formation of C₂H₅• (113.0 ± 8.4 kJ/mol = 27.0 ± 2.0 kcal/mol), •NO₂ (33.0 ± 0.4 kJ/mol = 7.9 ± 0.1 kcal/mol), and nitroethane (-102.5 ± 1.2 kJ/mol = -24.5 ± 0.3 kcal/mol) was found to be 248.5 ± 8.4 kJ/mol = 59.4 ± 2.0 kcal/mol. The activation energy of the abstraction of •NO₂, the primary step of the thermal dissociation of the nitroethane molecule, was estimated from kinetic measurements at 232.6 kJ/mol = 55.6 kcal/mol. The thermodynamic data in this 2008 publication differ slightly from data published by the same authors 2 years later. The dipole moment of nitroethane is 3.58 D, very similar to that of nitromethane, i.e., 3.54 D.

2.3 Chemical Properties of Nitroethane

The oxygen balance of nitroethane is -95.9% . This highly negative number alone already indicates that nitroethane would not be a good monopropellant by itself. It is highly oxygen deficient and must be mixed with a better oxidizer to formulate monopropellants with a decent performance and clean (soot-free) exhaust.

The term “alpha-effect” has been used to describe the high reactivity of nucleophiles possessing an unshared pair of electrons adjacent (α position) to the nucleophilic atom. The hydrogen in the α position is still quite acidic, although not as strongly as in nitromethane. The pK_a of nitroethane is only 8.46 compared to 10.18 for nitromethane.

The pK constants for conversion of nitroethane to its ion by amine neutralization of the anion were correlated by the Brønsted equations for general acid and general base catalysis [12]. The so-called α effect does not appear to be operative in the making of the C–H bond of nitroethane.

2.3.1 Thermal Decomposition of Nitroethane

2.3.1.1 Experimental Study of the Thermal Decomposition of Nitroethane

The decomposition reaction of nitroethane proceeds in principle following the same mechanism as that of nitromethane, a thoroughly studied decomposition reaction. Extrapolating from nitromethane to nitroethane and nitropropane gives some understanding of the effects of adding a methyl or an ethyl group to the carbon skeleton on the thermal stability of nitro compounds. The decomposition of nitroethane, 1-nitropropane, and 2-nitropropane was studied as a flow of 5–10% nitroalkane in nitrogen in a flow-through reactor, and the undecomposed nitro compound was captured in a cold trap at the exit of the reactor [13, 14]. The main difference is the increased formation of uncombusted pyrolysis products such as HCN, aldehydes, olefins, and the usual CO_2 and NO_x . The rate constant for the first-order decomposition of nitroethane was

$$k = 10^{10.83} \exp(-29700/RT) \text{ s}^{-1}$$

over the temperature range 593–713 K (320–440 °C). The equation matched data obtained in both static and flow systems, and was consistent with the postulated activated complex having a ring structure. In the range 763–808 K (490–535 °C), a special fast-flow system was used and gave the rate constant

$$k = 10^{17.56} \exp(-50600/RT) \text{ s}^{-1}$$

The activation energy approximated the C–N bond strength at these temperatures, and it appeared that a non-chain branched mechanism with initial fission of the C–N bond can account for the results at high temperature.

An accelerating rate calorimeter (ARC) was used to test the thermal stability of nitroethane in comparison to four solid explosives and 2-ethylhexyl nitrate (EHN) [15]. Kinetic and thermodynamic parameters were calculated and analyzed. Time to maximum rate under adiabatic conditions (TMR_{ad}) was calculated. Nitroethane was the thermally most stable material in the group of energetic materials tested. The thermal sensitivity (sensitivity is the opposite of stability) ranking of six energetic materials from high to low was EHN > pentaerythritol tetranitrate (PETN) > 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX) > 1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane (HMX) > 2,4,6-trinitrotoluene (TNT) > nitroethane. See also [16].

2.3.1.2 Theoretical Study of the Thermal Decomposition of Nitroethane

Some decomposition pathways of nitroethane (**1**) and 2-nitropropane (**2**) were studied computationally [17]. It was found that the concerted molecular elimination pathway is the most favorable decomposition channel, but other potentially important mechanistic routes were also investigated. It was found that the elimination of HONO in both nitroalkanes proceeds through relatively high barriers of 176 and 164 kJ/mol (42.0 and 39.2 kcal/mol), respectively. These values agreed well with the activation energies predicted by others on the basis of experimental results. The enthalpies of formation of

(1) and (2) were also calculated, and it was found that the enthalpies of formation predicted in this way, i.e., -104 ± 4 kJ/mol and -142 ± 4 kJ/mol (-24.5 ± 1 kcal/mol and -34.0 ± 1 kcal/mol), were indeed accurate enough for practical purposes.

The reaction mechanism and kinetics of thermal decomposition of nitroethane were studied by density-functional theory calculations, automatic pressure-tracking adiabatic calorimeter (APTAC) measurements, and gas chromatography analysis [18]. The APTAC results were used to derive kinetic rate equation parameters, giving pre-exponential coefficient of $A = 10^{13.5 \pm 0.2}$ and $E_a = 192 \pm 2.1$ kJ/mol = 46.2 ± 0.5 kcal/mol. The decomposition process included three initial steps: concerted molecular elimination of HONO, nitro–nitrite isomerization, and rupture of the C–NO₂ bond. A detailed mechanism consisting of 23 elementary steps was proposed and compared to the experimental results. Numerical simulations of the proposed mechanism reproduced the distributions of major products over the temperature range reasonably well. It was found that the relative concentrations of NO and C₂H₄ depended on the reaction temperature. Combining theoretical and experimental studies, it was concluded that elimination of HONO is predominant at low temperatures and dissociation of C–NO₂ becomes significant at higher temperatures.

Similarly, four distinct pathways of unimolecular decomposition of nitroethylene, i.e., C–NO₂ bond breaking, nitro-to-nitrite rearrangement, 1,2-elimination reaction, and 1,1-elimination reaction, have been computationally investigated with *ab initio* methods as well as with density functional theory (DFT) methods [19]. The nitro-to-nitrite rearrangement and 1,2-elimination reactions were found to give the lowest energy decomposition pathways for this molecule, about 15 kcal/mol lower than the cleavage of the nitro group.

2.3.2 Photolysis of Nitroethane

The photolysis of nitromethane had been investigated for decades to identify reactions that might precede the initiation of nitromethane decomposition in a rocket engine by laser ignition. Similarly, the photodissociation of gaseous nitroethane at 266 nm has been studied by monitoring the NO(*X*²Π) product using a laser-induced fluorescence technique [20]. For comparison, the geometries of the nitroethane, the ethyl nitrite, and the transition state connecting the two isomeric structures were then investigated using *ab initio* methods. The photodissociation dynamics of nitroethane can be explained on the basis of experimental observations and calculation results.

2.3.3 Shock-Tube Decomposition of Nitroethane Vapor

A shockwave study of the thermal decomposition of nitroethane in excess Ar at temperatures $900 < T < 1350$ K and total concentrations of $4.5 \times 10^{-6} < [\text{Ar}] < 3 \times 10^{-4}$ mol cm⁻³ showed that C–N bond fission

is the primary reaction step [21]. This unimolecular reaction could be observed in its transition region near the high-pressure limit. The derived rate constants were

$$k_{\infty} = 10^{15.9} \exp(-57 \text{ kcal mol}^{-1}/RT) \text{ s}^{-1}$$

for the high-pressure and

$$k_0/[Ar] = 10^{18.0} \exp(-36 \text{ kcal mol}^{-1}/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

for the low-pressure limit at $T \approx 1100\text{--}1200$ K. The observed concentration profiles of $\text{C}_2\text{H}_5\text{NO}_2$ and NO_2 indicated the subsequent decomposition of the ethyl radical

This reaction was found to be in the fall-off range under the given conditions.

2.4 Toxicity of Nitroethane

Nitroethane differs from nitromethane in that it exhibits anesthetic properties: stupor, narcosis, or light general anesthesia appeared in animals exposed to 30000 ppm in air for longer than 1 h or to 1000 ppm for 5 or 6 h [1].

Animal studies indicated that, regardless of the route of exposure, the liver is the organ that suffers the most severe damage from nitroethane poisoning. At necropsy, all exposed animals were found to have some liver damage; fatty infiltration was seen in a number of animals. Animals that died from nitroethane inhalation also exhibited general visceral and cerebral congestion, severe congestion of the upper respiratory tract, and pulmonary congestion with edema. Nitroethane was a relatively weak methemoglobinic poison compared to 1- or 2-nitropropane. Toxicity data for nitroethane from several sources are listed in Table 3.

Table 3: Acute effects of nitroethane toxicity.

Route	Species	Dose, mg/kg	Response
Oral	Rats	1625	LD50
Oral	Rats	1100	LD50
Oral	Mice	2150	LD50
Oral	Mice	860	LD50
Oral	Rabbits	500	LDLo
Inhalation	Rabbits	5000 ppm x 2 h	LcLo

Data source: [1]

Groups of rats were exposed in inhalation chambers to vapors of nitroethane at concentrations of 100 or 200 ppm, 7 h/d, 5 d/week for 2 years [22]. During the study, general observations were made daily and body weights were obtained weekly for the first 6 months of the study. Any rats that were found dead or sacrificed moribund during the 2-year exposure phase of the study were given a thorough gross examination and tissues were retained for microscopic analysis. After 2 years of inhalation of nitroethane, all surviving rats were sacrificed and subjected to the same thorough gross examination. Exposure of the rats to nitroethane had no pharmacologic effects nor were there any effects on mortality of rats at either level of exposure. There were no effects of exposure to nitroethane on hematology nor were there any biologically significant effects of exposure to nitroethane on clinical chemistry or on organ weights. No significant non-neoplastic or neoplastic pathology was found as a consequence of exposure of rats to nitroethane.

2.4.1 Maximum Allowable Exposure Limits for Nitroethane Vapors

The National Institute for Occupational Safety and Health (NIOSH) recommended exposure limit (REL) time-weighted average concentration (TWA) for nitroethane is 100 ppm (310 mg/m³) and the US Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) TWA is 100 ppm (310 mg/m³) for 40 h/week exposures. The NIOSH immediately dangerous to life or health (IDLH) concentration is 1000 ppm and remained unchanged from the original IDLH issued a few years earlier. The chosen IDLH was based on older observations that exposure to 5000 ppm for 2 h was lethal to one of two rabbits and to zero of two guinea pigs, and exposure to the same concentration for 3 h was fatal for two of two rabbits and to none of two guinea pigs [23].

2.5 Flammability of Nitroethane

The autoignition temperature of nitroethane in air is 688 K (779 °F). The open-cup flash point of nitroethane in air is 301 K (82 °F). Other sources gave a Tag open-cup flash point of 314 K (41 °C = 106 °F). The flammable range of nitroethane in air is 3.4–99 vol%.

2.6 Explosive Properties of Nitroethane

The section on *n*-propyl nitrate in *Encyclopedia of Oxidizers*, chapter Nitrate Esters, contains a comparison of the adiabatic compression sensitivities of nitromethane, nitroethane, and *n*-propyl nitrate [24]. Nitroethane was the least sensitive of the three liquids tested, with the energy required to initiate an explosion in 50% of the tests being the highest of the three.

Bulk nitroethane may be less detonable than other nitro compounds, but in aerosol mixtures of nitroethane mist in air, detonability is just as severe as with many other nitro compounds. A series of experiments was conducted with two different aerosol droplet diameters and the explosion pressure and temperature of the two sets of vapor–liquid mixtures of nitroethane/air at various concentrations were analyzed [25]. Similar experiments were conducted with isopropyl nitrate and/or JP-10 aerosols in air.

2.7 Applications of Nitroethane

Nitroethane is often added to nitromethane to render it less sensitive. This can only be justified if one can prove that nitroethane is less sensitive than nitromethane. Similar to nitromethane, nitroethane is widely used as a solvent for lacquers, paints, inks, coatings, and adhesives. It can be used as an additive to diesel fuels to increase power and to reduce smoke in exhaust. It is a good solvent for most nitro-organic explosives.

3 Higher ($C_{n>2}$) Mononitroalkanes

The most widely used $C_{n>2}$ nitroalkane is 2-nitropropane, $(H_3C)_2CHNO_2$, $C_3H_7NO_2$, CAS RN [79-46-9]. It is formed as a by-product during production of the lower nitroalkanes by reaction of nitric acid with propane.

3.1 Physical Properties of Higher Mononitroalkanes

Higher mononitroalkanes containing more than three carbon atoms have not been considered as rocket propellants. They are sometimes used as additives to energetic mixtures or as fuels in combination with other oxidizers. Higher nitroalkanes are less shock sensitive than nitromethane or propyl nitrate, but would give a lower specific impulse and the exhaust would be very sooty if they were used as monopropellants by themselves without any supplemental oxidizer. Properties of higher mononitroalkanes are summarized in Table 4.

Nitrobutane may form by radiolysis of tributyl phosphate/nitric acid mixtures used in the two-phase extraction of radionuclides from spent nuclear reactor fuel rods.

The heats of combustion of nitroalkanes and other organic nitrogen compounds can be extrapolated using a simple method [26] (“Upper heat of combustion” column in Table 4).

Physical and thermodynamic properties of C_1 – C_4 mono- and polynitroalkanes were determined and tabulated as shown in Table 5. The heats of combustion of the

Table 4: Physical properties of higher ($C_{n \geq 2}$) mononitroalkanes.

Compounds	Property

^a Energy for constant-volume reaction in a combustion bomb. This is not enthalpy of combustion.

nitroparaffins have been shown to be a linear function of the oxygen balance of the molecules, and an equation was derived that relates these two variables with an average error of about 2% of the experimental values. However, the number listed for the enthalpy of formation of nitromethane in Table 5 differs substantially from more reliable and more recent data which show an enthalpy of formation of -113.1 kJ/mol for liquid nitromethane.

The heats of combustion and heats of formation of the two isomeric nitropropanes do not differ much. Based on heats of combustion of 481.8 ± 0.7 and $478.0 \pm 0.3 \text{ kcal/mol}$ determined calorimetrically, standard heats of formation of -165.3 ± 2.9 and $-180.7 \pm 1.2 \text{ kJ/mol}$ (-39.5 ± 0.7 and $-43.2 \pm 0.3 \text{ kcal/mol}$) have been calculated for 1-nitropropane and 2-nitropropane, respectively [9]. Other sources [28] gave $-45.32 \text{ kcal/100 g}$ or -168.9 kJ/mol for 1-nitropropane and $-44.69 \text{ kcal/100 g}$ or -192.8 kJ/mol for 1-nitrobutane. Additional data are shown in Table 8 (in the "Polynitroalkanes" section).

X-ray powder diffraction structural investigations of crystallized 2-nitropropane at low temperatures identified a crystalline phase, called the α phase, below 172 K [29]. This form exhibited a triclinic symmetry with the $P1$ space group, with unit cell parameters of $a = 1.0313(3) \text{ nm}$, $b = 0.5873(2) \text{ nm}$, $c = 1.6146(4) \text{ nm}$, $\alpha = 90.17(2)^\circ$, $\beta = 92.17(2)^\circ$ and $\gamma = 90.09(2)^\circ$, and $Z = 8$. At $T_t = 172 \text{ K}$, a structural transition was observed which changed to another phase, called β -phase (above T_t). This form contained four molecules per unit cell and showed $Pc2_1n$ symmetry: $a = 1.0141(3) \text{ nm}$, $b = 0.5855(2) \text{ nm}$, and $c = 0.8319(4) \text{ nm}$. The crystal structures differ in terms of the different conformations of $-\text{NO}_2$ nitro groups and in terms of the orientation of the propyl group in the unit cell.

3.2 Chemical Properties of Higher Mononitroalkanes

3.2.1 Reactions of Higher Mononitroalkanes

The hydrogen in the α position of nitropropanes is still quite acidic and can form *aci* salts, although the acidity is less than that of nitromethane. The $\text{p}K_a$ of 1-nitropropane is 8.98 and the $\text{p}K_a$ of 2-nitropropane is 7.67.

3.2.2 Thermal Decomposition of Higher Mononitroalkanes

The effect of pressure on the rates of decomposition of 2-nitropropane was measured at pressures up to 1.1 GPa [30]. The mechanisms of thermolysis were inferred from kinetic studies and product composition analysis: 2-nitropropane was less stable than nitromethane; elevated pressure accelerated its decomposition; it was believed to cyclize via the *aci*-form like nitromethane. For comparison, 2,2-dinitropropane does not have an α -hydrogen and cannot tautomerize. In earlier work it was found to have a homolytic mechanism at high pressure. Therefore, the decomposition pathways of

nitroalkanes in aprotic solvents are determined not only by the conditions but also by the availability of an α -hydrogen.

Addition of amines enhances the formation of *aci*-nitropropane. Solutions of 1- and 2-nitroalkanes were thermolyzed in the presence of amines at hydrostatic pressures up to 1.5 GPa, and their rates of decomposition were measured [31]. The probable mechanism of base-catalyzed decomposition involved a bimolecular reaction of the *aci*-nitroalkane with the nitronate ion to yield a carbonyl compound, its corresponding oxime, and a nitrite ion as the early rate-determining steps. The effects of pressure on the rates of decomposition of non-acidic nitroalkanes, i.e., 2,2-dinitropropane, and 2-methyl-2-nitropropane, were measured and used to infer the rate-controlling steps. Whereas 2,2-dinitropropane appeared to undergo rearrangement to a nitrite followed by homolysis to give acetone, NO, and NO₂, 2-methyl-2-nitropropane gave mostly isobutylene and HONO, probably via a five-membered cyclic transition state.

Nitric acid/2-nitropropane mixtures are sometimes used as a model compound to study pre-explosion reaction steps at high pressures. High-pressure Raman spectroscopy measurements on stoichiometric HNO₃/2-nitropropane mixtures in a diamond anvil cell at 0–20 GPa identified the intermediates of the first-step reactions [32]. The initiation of the chemical decomposition can be correlated with weakening of the N–O bonds in the mixture. The study of a mixture with H¹⁵NO₃ identified the origin of nitrogen formation and identified a possible chemical pathway.

Alkylamines are known to sensitize nitroalkanes to detonation. Some of this interaction may take place even in the presence of nitric acid and at high pressures [33]. High-pressure Raman spectroscopy measurements in a diamond anvil cell at 0–10 GPa on HNO₃/2-nitropropane/X (X=triethylamine, diethylamine, or water) ternary systems and HNO₃/2-nitropropane/water/Y (Y=triethylamine or diethylamine) quaternary systems showed that the presence of triethylamine, diethylamine, and/or water modifies the chemical behavior of the HNO₃/2-nitropropane model system at ambient and high pressure. At high pressure, decomposition of the HNO₃/2-nitropropane system has only been observed in the presence of triethylamine.

3.2.2.1 Shock Tube Decomposition of Nitropropane Vapor

The pyrolysis of 1- and 2-nitropropane vapor highly diluted in Ar has been studied in a shock tube at temperatures of 915 < *T* < 1200 K and total gas concentrations $7 \times 10^{-6} \text{ mol/cm}^3 < [\text{Ar}] < 1.5 \times 10^{-4} \text{ mol/cm}^3$ [34]. The reactions behind the shock waves were followed by recording light absorption-time profiles of the decomposing molecules and the produced NO₂. Under the conditions of the experiments, the primary reaction step in both cases was C–N bond fission:

The first-order rate constant k measured at concentrations of $[\text{Ar}] \approx 10^{-4} \text{ mol/cm}^3$ were:

$$n\text{-C}_3\text{H}_7\text{NO}_2 \quad k = 2.3 \times 10^{15} \exp(-55 \text{ kcal mol}^{-1}/RT) \text{ s}^{-1}$$

$$i\text{-C}_3\text{H}_7\text{NO}_2 \quad k = 2.4 \times 10^{15} \exp(-54 \text{ kcal mol}^{-1}/RT) \text{ s}^{-1}$$

At these concentrations the reactions are taking place near to the high-pressure limit. By varying the Ar concentrations over one order of magnitude, only a slight pressure dependence was found.

The kinetics of the thermal decomposition of 2-nitropropane vapor were investigated in a shock tube over the temperature range 970–1150 K under high dilution in argon at total pressures of 456–608 kPa (4.5–6 atm) [35]. The decay of 2-nitropropane and the production of NO_2 were followed spectrophotometrically at 276 and 405 nm, respectively. The unimolecular rate constant deduced from the loss of 2-nitropropane at the high-pressure limit was

$$k_\infty = 10^{14.55 \pm 0.13} \exp(E_{\text{act}}/RT) \text{ s}^{-1}.$$

where the activation energy is $226.8 \pm 15.9 \text{ kJ/mol}$ or $54.2 \pm 3.8 \text{ kcal/mol}$ (depending on the units used for R), T is the temperature in kelvin, and k_∞ is the rate constant in s^{-1} . The products of pyrolysis were identified and quantified by Fourier-transform infrared spectroscopy (FTIR) and gas chromatography (GC). The major products were NO , $\text{CH}_3\text{CH}=\text{CH}_2$, CO , CH_3CHO , C_2H_4 , and $(\text{CH}_3)_2\text{CO}$. The decomposition proceeded primarily through C–N bond fission, while the contribution from the five-center elimination of HONO accounted for less than 20% of the total loss of 2-nitropropane. A reaction mechanism that consisted of 81 elementary steps was proposed and accurately accounted for the overall pyrolysis process. Numerical simulations with the mechanism reproduced reasonably well the NO_2 vs. time profiles at different temperatures and the distributions of major reaction products over the temperature range studied. When the mechanism was subjected to sensitivity and principal component analysis, it was found that only 58 reactions in the mechanism are needed to faithfully reproduce the observed product distributions. The rate of pyrolysis of 2-nitropropanol appeared to be similar to that of 2-nitropropane over the temperature range studied, but had a much lower activation energy.

In a similar test, the thermal decomposition of 2,2-dinitropropane was investigated in a shock tube over the temperature range 970–1200 K under high dilution in argon at total pressures of 456–557 kPa (4.5–5.5 atm) [36].

3.2.3 Photolysis of Higher Mononitroalkanes

The one-photon, collision-free, UV (222, 249, and 308 nm) photodissociation of 2-nitropropane leads to several chemically distinct sets of products, including OH , HONO , and NO_2 [37].

3.3 Toxicity of Higher Mononitroalkanes

2-Nitropropane is a widely used volatile industrial solvent and its toxicity has been thoroughly researched. Although 2-nitropropane is not used as a rocket propellant, its toxic properties are reviewed here in detail as it has been used as a process solvent in the synthesis of other energetic compounds and in the demilitarization and extraction of nitro compounds from solid propellants and explosives. Accidental exposure of operating personnel to vapors or splashes of 2-nitropropane may occur during those operations. The toxicity, in particular the mutagenicity and carcinogenicity of 2-nitropropane, has been investigated for several decades in surprising detail, because the comparison with its less active isomer, 1-nitropropane, may explain the connection between chemical structure and toxicity or carcinogenicity, a criterion that is important for all nitro compounds, including those used as rocket propellants and explosives. 2-Nitropropane has served as a model compound for the study of the toxicity of all nitroalkanes. The questions that needed to be answered pertained to the path of metabolism that leads the toxicant to the target organ and the possible role of intermediates, such as isomerization of the $-\text{NO}_2$ group to $-\text{ONO}$, reduction to $-\text{NHOH}$, or formation of the *aci* form nitronate in alkaline medium. The answers to these questions helped to understand the toxicity of other nitro compounds, some of which are used as rocket propellants and explosives.

Unlike primary nitroalkanes, such as 1-nitropropane, the secondary nitroalkane 2-nitropropane is geno- and hepatotoxic. Nitroalkanes exist in equilibrium with alkane nitronates, particularly in alkaline media. Differences between nitroalkanes in terms of the content of nitronate tautomer at equilibrium are probably an important chemical determinant of their toxic potential [38].

A very detailed summary of the toxicity of 2-nitropropane has been published as part of an International Agency for Research on Cancer (IARC) Monograph [39].

3.3.1 Acute Inhalation Toxicity of Higher Mononitroalkanes (Animal Exposure Tests)

Additional data on the toxicity of 1-nitropropane and 2-nitropropane are available in a publication by NIOSH [1]. Table 6 and 7 are summaries of acute inhalation toxicity test results with rodents and cats.

1-Nitropropane, when administered by intra-peritoneal (IP) injection, was found to be more toxic than 2-nitropropane. The minimum dose required to kill rats within 4 h was 550 mg/kg of 1-nitropropane compared to 1100 mg/kg of 2-nitropropane. By the respiratory route, however, 1-nitropropane was clearly less toxic than 2-nitropropane. One 8-h exposure of 800 ppm 2-nitropropane caused the death of rats in 48 h, but three 8-h exposures of 800 ppm 1-nitropropane were necessary to cause death in a similar group of rats. The liver is the target organ that suffers the most severe damage from 1-nitropropane poisoning. Occupational exposure to 1-nitropropane rarely occurs with this compound alone, it is usually associated with exposure to 2-nitropropane.

Table 6: Acute toxicity of 2-nitropropane in animal tests.

Route	Species	Dose, mg/kg	Response
Oral	Rats	725 ± 160	LD50
Oral	Rats	500	LDLo
Oral	Mice	400	LD50
Oral	Rabbits	500	LDLo
Intra-peritoneal	Mice	75	LDLo
Inhalation	Rats	1513 ppm × 4.5 h	LCLo
Inhalation	Rats	3865 ppm × 1 h	LCLo
Inhalation	Rats	2773 ppm × 1 h	LCLo
Inhalation	Rats	3712 ppm × 1 h	LC50
Inhalation	Rats	400 ppm × 6 h	LC50
Inhalation	Rats	5098 ppm × 1 h	LC100
Inhalation	Rabbits	2381 ppm × 4.5 h	LCLo
Inhalation	Guinea pigs	4622 ppm × 4.5 h	LCLo
Inhalation	Cats	714 ppm × 4.5 h	LCLo

Data source: [1]

Table 7: Acute toxicity lethal concentration data for 2-nitropropane.

Species	Refer- ence	LC50 (ppm)	LCLo (ppm)	Time	Adjusted 0.5-hr LC (CF)	Derived value
Rat	[40]	400	—	6 h	1535 ppm (2.15)	92 ppm
Cat	[41]	—	714	5 h	5119 ppm (2.15)	154 ppm
Rabbit	[41]	—	2381	5 h	4324 ppm (1.6)	512 ppm
Guinea pig	[41]	—	4622	5 h	9937 ppm (2.15)	994 ppm
Cat	[41]	—	2353	1 h	2941 ppm (1.25)	294 ppm

Nitropropanes dissolve readily in fat tissue and are transported with the blood. Several publications have studied the toxicokinetics of 2-nitropropane in the body, the distribution between inhaled air and absorbed toxicant in the body, and the pathway from the lung to the tissue that suffered the most damage (i.e., the liver). Toxicokinetics of atmospheric 2-nitropropane (2-NP) were investigated in rats and rabbits [42–44]. A thermodynamic partition coefficient (body/air) was obtained from the data obtained *in vivo*. A similar value of the thermodynamic partition coefficient was calculated from the *in vitro* accumulation of atmospheric 2-NP in water and olive oil. Due to metabolism in the animals, the actual concentration at steady state was less than the former values of the thermodynamic partition coefficient, declining to 22–30 at concentrations below 10 ppm. 2-NP was found to be metabolized via two pathways: a non-saturable pathway according to first-order kinetics, which was quite similar in both sexes and all species; and a saturable pathway. The path of the toxicant in the body can be traced by using isotope-labeled nitropropane [45]. Rats were exposed by

inhalation for 6 h to 20 or 154 ppm of 2- $[^{14}\text{C}]$ nitropropane (2- $[^{14}\text{C}]$ NP) and the distribution of radioactivity in these animals was followed for 48 h. These data indicated that at least 40% of the inhaled 2- $[^{14}\text{C}]$ NP was absorbed. 2- $[^{14}\text{C}]$ NP was rapidly metabolized and eliminated, and thus had a low potential for accumulation in the rat during prolonged or repeated exposures.

Groups of rats were exposed by inhalation to vapors of 1-nitropropane at 100 ppm for 7 h/d, 5 d/week, for periods up to 21.5 months [46]. Groups of rats were killed after 1, 3, 12, and 18 months of exposure, and additional groups of exposed rats were removed from the exposure chamber after 3 and 12 months and held under non-exposure conditions for the remainder of the study. The results of gross necropsies of the animals did not disclose any adverse effects of exposure to 1-nitropropane in any of the organs or tissues. There were no histopathologic changes of the liver and, in particular, no induction of hepatocarcinoma. No effects were observed on final body weights or the weights of liver, kidney, or brain.

Groups of rats were exposed to vapors of 1-nitropropane or 2-nitropropane at concentrations of 100 ppm for 7 h/d on 4 consecutive days [47]. Livers were analyzed for enzymatic activities after 1-, 2-, and 4-day inhalation periods. Liver microsomal cytochrome P450 was depressed by 2-nitropropane but elevated following exposure to 1-nitropropane. Changes in other liver enzymes during a 4-d exposure period were observed in both of the exposed groups in comparison to control animals.

3.3.2 Chronic Inhalation Toxicity of Higher Mononitroalkanes (Animal Exposure Tests)

The effect of 2-nitropropane vapor on a number of species was tested and the animals were found to be affected in the following order of decreasing sensitivity: cats, rats, rabbits, and guinea pigs [41]. Rats, rabbits, and guinea pigs survived repeated 7-h exposures (five times weekly for 130 exposures at 328 ppm); cats (and a monkey) survived 83 ppm over the same period. The highest concentrations tolerated for 4.5 h without significant effect were 328 ppm for cats, 714 ppm for rats, 1401 ppm for rabbits, and 2381 ppm for guinea pigs. The lowest lethal concentrations for 4.5 h were 714 ppm for cats, 1513 ppm for rats, 2381 for rabbits, and 4622 for guinea pigs. Symptomatic effects resulting from sufficiently high concentrations were similar in all species and included dyspnea, cyanosis, prostration, convulsions, and coma. Pathologic changes in animals exposed to 2353 ppm were generalized vascular endothelial damage in all tissues associated with pulmonary edema and hemorrhage. No pathology was seen in rats, rabbits, or guinea pigs following repeated exposure to 328 ppm, but cats showed severe liver damage and slight to moderate degeneration of the heart and kidneys. Formation of methemoglobin and Heinz bodies in the erythrocytes occurred in proportion to the concentration and duration of exposure. Based on these results, a safe concentration of 50 ppm was recommended as the threshold limit value (TLV) for human exposure at the workplace.

The effects of 2-nitropropane administered by both intra-peritoneal injection and inhalation in the rat were investigated in France [48].

Groups of rats were exposed by inhalation to 2-nitropropane at a concentration of 25 ppm for 7 h/d, 5 d/week, over a period of 22 months [49–51]. Periodic examinations of serum chemistry, hematology, and histopathology were conducted throughout the study. All animals remaining alive were sacrificed after 22 months. No effects on serum chemistry or hematology were observed which could be attributed to exposure of the animals to 2-nitropropane. There was no methemoglobinemia and thus no apparent large release of nitrite. No malignancies or significant pathologic changes were observed in the livers of any of the rats. Focal areas of hepatic, cellular nodules were noted in 3 of 250 control animals and 13 of 249 exposed animals.

For sub-chronic exposure, two guinea pigs, two rats, and one rabbit survived exposure to 328 ppm 2-nitropropane in air 7 h/day, 5 days/week, administered over a 199-day period. Cats, however, did not survive at this concentration; one died after the third exposure period and another died after the seventeenth exposure period. 2-Nitropropane is a carcinogen: all 10 Sprague–Dawley rats exposed by inhalation to 207 ppm 2-nitropropane for 6 months developed hepatocellular carcinoma or hepatic adenoma.

In a study for NIOSH, in all 10 rats that had received 6 months of exposure to 207 ppm 2-nitropropane, multiple hepatocellular carcinomas were present [40]. These carcinomas appeared to be highly malignant. Liver weights were significantly elevated in rats exposed to 207 ppm of 2-nitropropane for 1, 3, and 6 months. No exposure-related gross or microscopic alterations were seen in any of the tissues examined for rats and rabbits exposed to 27 ppm of 2-nitropropane or in tissues of rabbits exposed to 207 ppm of 2-nitropropane. Liver neoplasms were seen in all 10 rats killed following 6 months of exposure to 207 ppm of 2-nitropropane, indicating that 2-nitropropane is a potent carcinogen in the rat.

In another study, groups of rats were exposed to 25 ppm 2-nitropropane 7 h/d, 5 d/week, for periods up to 22 months. At the end of the exposure period, no malignancies or any significant pathologic changes attributable to 2-nitropropane exposure had been observed in any tissues.

Groups of rats were exposed to 207, 200, 100, 27, or 25 ppm 2-nitropropane for up to 6 months [52]. Liver changes such as hepatocellular hypertrophy, hyperplasia, necrosis, and liver tumors occurred in rats exposed to 207 ppm. Rats exposed to 100 ppm developed liver tumors.

3.3.3 Toxicity of Higher Mononitroalkanes by Other Methods of Administration (Other than by Inhalation)

Intra-peritoneal injection (50 mg/kg) of 2-nitropropane induced lipid accumulation, centrilobular necrosis, degranulation of rough endoplasmic reticulum, proliferation of smooth endoplasmic reticulum, and mitochondrial abnormalities in rat liver 24 h

after exposure [53]. These pathological changes were accompanied by elevated serum alanine aminotransferase levels. Hepatic glutathione content increased rapidly in exposed rats. The results suggest peroxidative damage in the cells.

Depending on the mode of administration, 1-nitropropane was significantly less toxic than 2-nitropropane. The oral lethal dose 50% (LD50) in male rats was 528 mg/kg and the oral LD50 in female rats was 484 mg/kg. The cutaneous absorption and distribution of absorbed ¹⁴C-1-nitropropane in female Rhesus monkeys showed a relatively benign response [54, 55].

3.3.4 Mutagenicity of Higher Mononitroalkanes

2-Nitropropane was mutagenic in *Salmonella typhimurium* [56]. The mutagenicity of 2-nitropropane and the relative inactivity of 1-nitropropane in *Salmonella* was confirmed, and the *in vitro* DNA-modifying activity of 2-nitropropane presented evidence to suggest that the genetic activity of this nitroalkane may not be dependent on the enzymatic reduction of the —NO₂ group to the corresponding hydroxylamine [57].

A 10- and 12-fold increase of revertant numbers was observed for 2-nitropropane as tested in the preincubation assay with *S. typhimurium* strains TA 100 and TA 98 in the presence and absence of an activator [58]. In the nitroreductase-deficient strains TA 100NR and TA 98NR, 2-nitropropane was less mutagenic than in the parent strains. In human lymphocytes, the induction of a weak clastogenic effect and of sister chromatid exchanges required exogenous metabolic activation. No significant mutagenic or cytogenetic response was found with 1-nitropropane in *S. typhimurium* or human lymphocytes.

Chromosome analyses were carried out in human lymphocytes treated *in vitro* with 2-nitropropane in the presence and absence of a mammalian metabolic activation system [59]. 2-Nitropropane was weakly clastogenic in human lymphocytes. Sister chromatid exchanges (SCE) were induced at concentrations as low as 7.5 mM.

The genotoxicity of 2-nitropropane and 1-nitropropane was investigated by measuring the induction of DNA repair synthesis in rat liver cells *in vitro* and *in vivo*: 2-nitropropane strongly induced DNA repair synthesis in both cases [60]. 2-Nitropropane was genotoxic in mammalian systems *in vitro* and *in vivo*; 1-nitropropane was not active *in vitro* or *in vivo*.

The structural isomer of 2-nitropropane, 1-nitropropane, was less hepatotoxic [61] and did not show genotoxicity in *Salmonella typhimurium*. It was, however, found to be mutagenic in the V79 Chinese hamster cells assay [62] and increased unscheduled DNA synthesis in rat hepatocytes *in vitro* [63]. Genotoxicity was much weaker or undetectable in cells not pre-treated with the inducer. 1-Nitropropane was not genotoxic in the hepatoma cells, irrespective of whether the cells were pre-treated or not.

2-Nitropropane is a rat liver carcinogen, whilst the 1-isomer is non-carcinogenic in rodents. Although DNA repair tests in rat liver discriminated clearly between the carcinogenic and the non-carcinogenic isomer, uniformly negative results have been

published for the mouse bone marrow micronucleus test with both isomers [63, 64]. Both 2-nitropropane and its anionic form, propane-2-nitronate, were mutagenic, but the nitronate was the more powerful mutagen [65]; however, nitroreduction is not involved in the genotoxicity of 2-nitropropane in cultured mammalian cells [66].

3.3.5 Carcinogenicity of Higher Mononitroalkanes

Based on studies in animals, 2-nitropropane is reasonably anticipated to be a human carcinogen and is listed as an IARC group 2B carcinogen [67]. When tested under the same conditions as 2-nitropropane, 1-nitropropane was not carcinogenic in rats after oral administration [68]. Groups of 4–6-day-old rats were exposed for 3 weeks (6 h/d, 5 d/week) to 2-nitropropane vapors of 0, 25, 40, 50, 80, and 125 ppm. One week later, polychlorinated biphenyls were administered for promotion twice a week for 8 weeks. The logarithms of the numbers of pre-neoplastic liver foci were found to be linearly related to the exposure concentrations of 2-nitropropane [69].

3.3.6 Accident History of Higher Mononitroalkanes

Humans may not be able to detect 2-nitropropane by its odor, even in the presence of potentially hazardous concentrations. One report stated that humans cannot detect 2-nitropropane at 83 ppm by its odor. Another stated that 2-nitropropane cannot be detected by its odor until the concentration reached about 160 ppm. Nausea, vomiting, diarrhea, anorexia, and severe headache have been reported in workers exposed to daily concentrations of 20–45 ppm.

Reports of four fatal poisonings by inhalation of paint fumes containing 2-nitropropane followed by detailed autopsies of the victims should have alerted the authorities to the hazards of working with this solvent, yet it continued to be used [70].

Two construction workers became ill after applying an epoxy resin coating containing 2-nitropropane in the confined, poorly ventilated space of an underground concrete vault [71]. One man died 10 d later from fulminant hepatic failure. The second man recovered but had persistently elevated serum aminotransferase activity. There have not been sufficient warnings about the acute toxicity of 2-nitropropane despite repeated reports of death due to hepatic failure after exposure to the compound in confined spaces.

3.3.7 Established Exposure Limits for Higher Mononitroalkanes

The occupational exposure standard recommended by the American Conference of Governmental Industrial Hygienists (ACGIH; 1981) for 2-nitropropane was a threshold limit value time-weighted average (TLV-TWA) of 25 ppm (90 mg/m³) [72].

NIOSH considers 2-nitropropane to be a potential occupational carcinogen as defined by the OSHA carcinogen policy [73, 74].

- OSHA PEL: 25 ppm (90 mg/m³) TWA
- 1989 OSHA PEL: 10 ppm (35 mg/m³) TWA
- 1993–1994 ACGIH TLV: 10 ppm (35 mg/m³) TWA, A2

The IDLH chosen in the 1970s was based on the observation that the lowest lethal concentration for cat for a 1-h exposure was found to be 2353 ppm. The response of different species to 2-nitropropane varied considerably, but cat was the most sensitive species in this investigation [41].

The revised and currently valid IDLH for 2-nitropropane is 100 ppm, based on acute inhalation toxicity data in animals. This may be a conservative value due to the lack of relevant acute toxicity data for workers exposed to concentrations above 45 ppm [75, 76]. (Note: NIOSH recommends as part of its carcinogen policy that the “most protective” respirators be worn for 2-nitropropane at any detectable concentration.)

3.4 Safety Properties of Higher Mononitroalkanes

The autoignition temperature of 2-nitropropane in air is 701 K (802 °F). The Cleveland flash point of 2-nitropropane in air is 313 K (103 °F). The Tag open-cup flash points of 1-nitropropane and 2-nitropropane in air are 322 and 311 K (120 and 100 °F), respectively.

4 Higher Polynitroalkanes

4.1 Physical Properties of Higher Polynitroalkanes

Attaching more than one nitro group to an alkane will improve the oxygen balance and create a multitude of potentially very energetic compounds. Attaching more than one nitro group to an alkane backbone will create various isomers. The nitro groups influence each other and adjacent hydrogens [77]. The physical properties of several polynitroalkanes have already been listed in previous tables along with those of the mononitroalkanes.

4.1.1 Thermodynamic Properties of Higher Polynitroalkanes

Most theoretical computations of thermodynamic data for energetic materials show only results for molecules in the vapor phase, which is of very limited use to the experimental propellant chemist. Computations giving the numbers for energetic com-

pounds in the condensed phase state are lacking. The heat of combustion of 2,2,3,3-tetranitrobutane, $C_4H_6(NO_2)_4$, is 2452 kJ/mol (586.1 kcal/mol) [26].

As part of an evaluation of hexanitroethane/fuel mixtures as monopropellants, the enthalpies of formation of several other polynitroalkanes were tabulated as shown in Table 8.

Table 8: Enthalpy of formation of polynitroalkanes.

Compound	Gross formula	Molecular mass, g/mol	Mols/kg	Enthalpy of formation			
				kcal/100 g	kcal/kg	kcal/mol	kJ/mol
Hexanitroethane	$C_2N_6O_{12}$	300.05	3.3328	9.53	95.3	28.59	119.6
1-Nitropropane	$C_3H_7NO_2$	89.09	11.2246	-45.32	-453.2	-40.38	-168.9
1-Nitrobutane	$C_4H_9NO_2$	103.12	9.6974	-44.69	-446.9	-46.08	-192.8
1,1-Dinitroethane	$C_2H_4N_2O_4$	120.06	8.3292	-28.87	-288.7	-34.66	-145.0
1,1-Dinitropropane	$C_3H_6N_2O_4$	134.09	7.4577	-29.85	-298.5	-40.03	-167.5
1,1,1-Trinitropropane	$C_3H_5N_3O_6$	179.09	5.5838	-15.66	-156.6	-28.05	-117.3

Data source: [28]

A comparison of results from Modified Intermediate Neglect of Differential Overlap, version 3 (MINDO/3), Modified Neglect of Differential Overlap (MNDO), and Austin Model 1 (AM1) calculations to each other and also to available experimental data for 105 nitro compounds, both aliphatic and aromatic, gives data only for the vapor phase. The properties evaluated include heats of formation, dipole moments, ionization potentials, and molecular geometries. In general, MINDO/3 predicted heats of formation, dipole moments, and ionization potentials more accurately than MNDO and AM1 [78, 79].

Table 9 provides a summary of enthalpies of formation for condensed-phase and vapor-phase polynitro compounds derived from methane and ethane. This is a useful table for comparisons in this group of potential rocket propellants and explosives. As a baseline, the heats of combustion of the condensed-phase species are also listed, because the experimentally measured enthalpies of formation are often derived from these numbers. This table is useful when studying the effects of interaction between neighboring multiple nitro groups in polynitroalkanes.

In nitroalkanes with one or two separated nitro groups, the enthalpy of formation can be predicted fairly accurately using one of the conventional rules of additivity of bond energies [81]. With increasing number of nitro groups on a methane or ethane skeleton, the efficient energy of interaction (EEI) among nitro groups increases and results in a measurable difference between measured and theoretically predicted enthalpies of formation for the gas-phase molecules. The actual enthalpy of formation is lower than the enthalpy predicted without the knowledge of interaction between the nitro groups [80] (Table 10). In nitromethanes, the dissociation energy of the C-NO₂ bonds decreases from 254 to 176 kJ/mol (60.8 to 42.2 kcal/mol) while go-

ing from nitromethane to tetranitromethane. Similar interactions are also observed in polynitrobenzenes. See also [82].

In order to compare computational results for 28 aliphatic nitro compounds in the gaseous state with experimental results of 19 compounds, correlation models were established by multivariable linear regression methods considering the number of nitro

groups and use of quadratic relations involving the number of carbon, hydrogen, nitrogen, and oxygen atoms [83]. Both the AM1 and the Parametric Method 3 (PM3) have good agreement with the experimental results. Based on these correlations, heats of formation of some aliphatic nitro compounds can be predicted with only $\pm 5\%$ deviations. Table 11 is a comparison of measured and calculated results. Results from only one of the calculating methods (PM3, Eq. 14) is shown here.

Table 11: Heats of formation of aliphatic nitro derivatives in the vapor phase.

Similar molecular orbital calculations were applied to energetic dinitro compounds based on inter-molecular binding energies, molecular geometries, molecular electrostatic potentials, and conformational energies of model compounds [84]. Non-bonded parameters were derived by fitting experimental densities and heats of vaporizations of model compounds. Torsional parameters were quantified to accurately reproduce the relative conformational energy minima and barriers in 2,2-dinitropropane, bis(methoxymethyl) ether, 2,2-dinitro-3-methoxypropane, and bis(2,2-dinitropropyl)formal, and calculations accurately reproduced thermodynamic and transport properties of 1,1-dinitroethane, 2,2-dinitropropane, and a eutectic mixture of bis(2,2-dinitropropyl)formal and bis(2,2-dinitropropyl)acetal.

Density functional theory (DFT)-based calculations were performed on a series of nitroalkanes and alkyl nitrites representing primary, secondary, and tertiary nitro compounds and their radicals resulting from loss of their skeletal hydrogen atoms [85]. Geometries, vibration frequencies, and thermochemical properties (S°_T and $C^\circ_{p(T)}$) in the temperature range from 10 to 5000 K were calculated by DFT methods and enthalpy of formation values via other methods. Potential energy barriers for the internal rotations were computed, and the lower barrier contributions were incorporated into entropy and heat capacity data. The standard enthalpies of formation of nitroalkane and alkyl nitrite vapors at 298 K were evaluated using iso-seismic reaction schemes with several work reactions for each species. Recommended standard enthalpy of formation values derived from the most stable conformers of respective nitroalkane and alkyl nitrite isomers include -127.9 and -119.0 kJ/mol (-30.57 and -28.44 kcal/mol) for 1-nitropropane and *n*-propyl nitrite, -141.8 and -135.2 kJ/mol (-33.89 and -32.32 kcal/mol) for 2-nitropropane and isopropyl nitrite, -179.0 and -173.0 kJ/mol (-42.78 and -41.36 kcal/mol) for 2-methyl-2-nitropropane and *tert*-butyl nitrite, respectively. For comparison, entropy and heat capacity values were also reported for the vapors of the lower homologues: nitromethane, nitroethane, and corresponding nitrites. See also [86].

4.2 Chemical Properties of Higher Polynitroalkanes

Higher polynitroalkanes are of interest as energetic compounds in propellants or explosives because potentially, so many nitro groups can be attached until the oxygen balance becomes positive. An example is hexanitroethane with an oxygen balance of $+42.7\%$. In addition, the acidity of the few remaining hydrogen atoms becomes so high that these compounds are quasi-acids and can form salts with a wide variety of bases [87]. The salts are also potential propellant additives, like the acid from which they are derived, or they serve as intermediates in the synthesis of other nitro compounds.

The following summary of polynitroalkanes is subdivided by the structure of the carbon skeleton to which the nitro groups are attached. The simplest polynitroalkanes are those with a straight carbon-carbon chain, starting with those based on a chain with only two carbon atoms, the ethane skeleton.

4.3 Sensitivity of Higher Polynitroalkanes

The thermal stability of $C_{n>2}$ polynitroalkanes is generally lower than that of nitromethane. One exception is 1,1-diamino-2,2-dinitroethene, which is a thermally stable explosive. The sensitivity of polynitroalkanes and nitramines to mechanical impact can be correlated to their molecular structure [88]. Similar relationships were established for polynitroaromatic explosives.

5 Straight-Chain Polynitroalkanes and Polynitroalkenes

Adding nitro groups to straight-chain $C_{n>1}$ nitroalkanes will make them more useful as oxidizers and monopropellants, but will in most instances render them less thermally stable and more chemically reactive. Most of the work has been done with polynitroethanes and less work with the higher $C_{n>2}$ polynitroalkanes.

5.1 Polynitroethanes

5.1.1 Dinitroethanes

The oxygen balance for combustion of dinitroethanes to CO_2 is -26.7% . There are two isomers of dinitroethane, the symmetrical 1,2-dinitroethane and the unsymmetrical 1,1-dinitroethane:

$O_2NCH_2CH_2NO_2$	$(O_2N)_2CHCH_3$
1,2-dinitroethane	1,1-dinitroethane
CAS RN [7570-26-5]	CAS RN [600-40-8]

5.1.1.1 1,2-Dinitroethane

1,2-Dinitroethane, $O_2NCH_2CH_2NO_2$, viz-dinitroethane, Chemical Abstracts Service Registry Number (CAS RN) [7570-26-5], molecular weight: 120.06416 g/mol, can be prepared in 70–80% yield by passing ethylene into dinitrogen tetroxide, N_2O_4 , at 263 K (-10°C). The use of a mixture of ethylene with oxygen in the volume ratio of about 4:1 gives good results. Ethylene reacts much more slowly than the higher olefins [89]. 1,2-Dinitroethane forms colorless crystals when crystallized from MeOH or benzene, melting point (m.p.) 312–313 K ($39\text{--}40^\circ\text{C}$), boiling point (b.p.) 408 K (135°C) at 5 mm pressure, density 1.460 g/cm³. It slowly decomposes on storage, turning acidic. It is insoluble in water. The explosive power measured by Trauzl lead block test was 146% of that of picric acid [90]. 1,2-Dinitroethane, its potassium salt, and dinitropropanol are intermediates in the synthesis of energetic plasticizers such as bis(2,2-dinitropropyl) acetal (BDNPA) and bis(2,2-dinitropropyl) formal (BDNPF). Therefore, more economical methods were sought for the production of 1,2-dinitroethane, including electrolytic nitrating methods.

Older sources [91] gave the heat of combustion of 1,2-dinitroethane as -1183 ± 1.2 kJ/mol (282.7 kcal/mol) and the heat of formation derived therefrom was -176 ± 1.2 kJ/mol (42.1 kcal/mol; previously reported number corrected for pressure). Other sources gave the heat of formation of 1,2-dinitroethane as -179 ± 0.8 kJ/mol (-42.8 kcal/mol) [4]. Table 12 gives the physical state of 1,2-dinitroethane at 298 K as a liquid, when actually the pure compound melts only at a higher temperature, 312–313 K. Impure specimens may be liquids at room temperature.

Table 12: Thermodynamic properties of dinitroethanes.

Compound	Physical state	Standard enthalpy of formation ΔH_f^{298}		Enthalpy of evaporation ΔH_{evap} at 298 K		Vapor state enthalpy of formation $\Delta H_f^{298}(\text{G})$	
		kJ/mol	kcal/mol	kJ/mol	kcal/mol	kJ/mol	kcal/mol
1,1-Dinitroethane	Liquid	-149.4 ± 0.4	-35.7 ± 0.1	61.1 ± 0.4	14.6 ± 0.1	-88.3 ± 0.8	-21.1 ± 0.2
1,2-Dinitroethane	Liquid	-178.2 ± 0.4	-42.6 ± 0.1	81.6 ± 0.8	19.5 ± 0.2	-96.7 ± 1.3	-23.1 ± 0.3

Data source: [8]

The molecular structure and theoretical dipole moments for different forms of 1,2-dinitroethane were calculated and compared to measured data. The known experimental value of the dipole moment of this compound ($\mu = 1.12$ D at 305 K = 32 °C) corresponds to a high proportion (~70%) of the *trans* form [92]. Measurements of 1,2-dinitroethane solutions in benzene at 293 K gave a dipole moment of 4.4 ± 0.1 D. The theoretical dipole moment of 1,2-dinitroethane was calculated as a function of the rotation angle separating the two nitro groups. If the two molecule halves were freely rotating, one would expect a dipole moment of 4.13 D, which is close to the measured value in solution.

The slow decomposition of 1,2-dinitroethane can be retarded by addition of aryl-sulfonic acids as stabilizers [93].

The gas-phase enthalpies of formation of 1,1-dinitroethane and 1,2-dinitroethane and the corresponding radicals were calculated using composite methods and DFT theory with various basis sets [94, 95]. The enthalpies of the C—N and C—C bonds dissociation and activation enthalpies for HONO elimination were calculated and compared with available experimental data. It was found that some calculations do provide a reasonable way to tackle the problem of the decomposition channels of 1,1- and 1,2-dinitroethane, including four main mechanisms for gas-phase decomposition of 1,1- and 1,2-dinitroethane: dissociation through direct breaking of the C—N bond, producing two radicals, $\text{C}_2\text{H}_4(\text{NO}_2)_2$, and NO_2 ; elimination of HONO; nitro–nitrite rearrangement; and finally, a mechanism of hydrogen transfer and isomerization to the *aci* form were studied. HONO elimination seemed to be the most favorable mechanism for the decomposition of 1,2-dinitroethane. However, the difference in energies of the HONO elimination and C—N homolytic bond cleavage in 1,1-dinitroethane does not favor any of these channels, especially at low temperature. The *gauche* conformation of 1,2-dinitroethane was predicted to be the lowest-energy minimum.

Examination of the infra-red (IR) and Raman spectra suggested that 1,2-dinitroethane exists in the polar *gauche* conformation in the solid state and as a mixture of the *gauche* and *trans* rotamers in solution [96]. Analysis of the dipole moment and relative permittivity data showed that at 298 K (25 °C) in solution, the compound existed in a ratio of approximately 92% *gauche* to 8% *trans*. The crystal and molecular structure of solid 1,2-dinitroethane was determined by single-crystal X-ray diffraction (XRD). The molecule crystallizes in the tetragonal space group $I4_1/a$, with $a = 13.305(1)$ Å, $c = 11.121(3)$ Å, $V = 1968.8(6)$ Å³, and $Z = 16$. The molecule adopts a *gauche* conformation with a N—C—C—N torsion angle of 73.5(2)°.

5.1.1.2 1,1-Dinitroethane

1,1-Dinitroethane, $(\text{O}_2\text{N})_2\text{CHCH}_3$, $\text{C}_2\text{H}_4\text{N}_2\text{O}_4$, *gem*-dinitroethane, CAS RN [600-40-8], molecular mass = 120.06416 g/mol, is a colorless oil with faint alcoholic odor with

a b.p. of 458–459 K (185–186 °C) at 760 mm Hg and of 346–347.6 K (73–74.5 °C) at 13 mm Hg, and a density of 1.4340 g/cm³ at 293 K (20°) and 1.3503 g/cm³ at 296.6 K (23.5 °C). The oxygen balance is –26.7%. The enthalpy of formation of 1,1-dinitroethane is –289 cal/g = –34.7 kcal/mol = –145 kJ/mol [97]. It forms salts with potassium [98] or sodium or ammonia which are explosive. The ammonium salt NH₃C₂H₃(NO₂)₂ is a yellow salt, m.p. 363–366 K (90–93 °C).

1,1-Dinitroethane, its potassium salt, and dinitropropanol are intermediates in the synthesis of energetic plasticizers such as 2,2-dinitropropyl acetal (BDNPA) and bis(2,2-dinitropropyl) formal (BDNPF). Therefore, more economical methods were sought for the production of 1,1-dinitroethane, including electrolytic nitrating methods [99]. Three methods of converting nitroethane to dinitroethane have been investigated: nitration, oxidative nitration, and oxidation of the readily formed ethylnitrolic acid. Attempts to substitute nitrite for chloride in 1,1-dichloroethane were unsuccessful. Other possible routes to dinitroethane are electrolytic nitration and nitrite displacement on chloronitroethane [100, 101]. The first step in electrolytic methods for the preparation of simple *gem*-dinitroparaffins is the electrolytic oxidation of a silver anode to silver ions [102]. In the preparation of 1,1-dinitroethane, the silver ions react in the anode compartment of the electrolysis cell with nitrite and ethylnitronate ions to form the potassium salt of dinitroethane in solution and silver metal on the surface of the electrode. 1,1-Dinitropropane and 2,2-dinitropropane have been prepared by analogous reactions.

The gas-phase enthalpies of formation of 1,1- and 1,2-dinitroethane and corresponding radical products of decomposition were calculated using density functional theory/orbital bond energy methods [103]. The enthalpies of the C–N and C–C bonds dissociation and activation enthalpies for HONO elimination were compared with available experimental data. It was found that calculations did provide a reasonable way to describe the decomposition channels of 1,1- and 1,2-dinitroethane. Four main mechanisms for gas-phase decomposition of 1,1- and 1,2-dinitroethane were identified. HONO elimination seemed to be the most favorable mechanism for the decomposition of 1,2-dinitroethane. However, the difference in energies of HONO elimination and C–N homolytic bond cleavage in 1,1-dinitroethane did not favor any of these channels, especially at the working temperature. The *gauche* conformation of 1,2-dinitroethane seemed to be the lowest-energy minimum.

5.1.2 Trinitroethanes

The oxygen balance of trinitroethanes for combustion to CO₂ is +8.45%.

1,1,1-Trinitroethane, (O₂N)₃CCH₃, C₂H₃N₃O₆, molecular mass: 165.0617, CAS RN [595-86-8], forms small white, very volatile cubic crystals with a m.p. of 329–330 K =

56–57 °C and a molten state-specific gravity of 1.4223 g/cm³ at 350.8 K = 77.7 °C. Distillation (with precautions!) is possible with a b.p. of 341 K = 68 °C at 2.26 kPa = 17 mm Hg reduced pressure [104].

1,1,1-Trinitroethane explodes at higher temperatures. 1,1,1-Trinitroethane is very soluble in water and soluble in ethanol, diethyl ether, and in most organic solvents.

The heat of combustion of solid 1,1,1-trinitroethane is -1103 ± 0.8 kJ/mol and the heat of formation is $-113. \pm 0.8$ kJ/mol [4]. The heat of fusion is 11.72 kJ/mol at 329.2 K [105]. The heat of sublimation is 72.0 ± 8.8 kJ/mol. The enthalpy of formation of solid 1,1,1-trinitroethane is -166 cal/g = -274 kcal/mol = -114.6 kJ/mol and the density is 1.528 g/cm³ = 0.0552 lb/in³ [97]. It detonates when hit by a hammer blow.

1,1,1-Trinitroethane can be prepared by the action of a cooled ethereal solution of silver nitroform on an excess of methyl iodide:

After allowing the mixture to stand for a short time, it is filtered to remove AgI and the filtrate is evaporated in a vacuum [106]. In another method of preparation, the more economical potassium salt of nitroform was dissolved in acetone and treated with methyl iodide [107]. Reaction of nitroethane with sodium methylate and then with tetranitromethane gives a mixture of 1,1,1-trinitroethane and 1,1-dinitroethane [108].

5.1.3 Tetranitroethanes

Tetranitroethane, C₂H₂(NO₂)₄, molecular mass 210.07, oxygen balance for combustion to CO₂ +22.8%, may exist in the form of two isomers. 1,1,2,2-Tetranitroethane, *sym*-1,1,2,2-tetranitroethane, (O₂N)₂CHCH(NO₂)₂, is not known in the free state, but its potassium, silver, and lead salts are known. The dipotassium salt is an explosive of the initiating class and is extremely sensitive to friction, impact, and heat, especially if not properly purified. This is a good reason not to use it as a rocket propellant. The salt was prepared at Picatinny Arsenal in 1930 and then again in 1947. However, the compound was considered too dangerous for use as a military explosive and work on it discontinued after what was supposed to be some of the salt exploded in a beaker resulting in the death of a chemist, Dr. P. F. Macy.

The crystal structure of dipotassium tetranitroethide, K(NO₂)₂CC(NO₂)₂K, has been determined by single crystal XRD [109]. The compound crystallizes in the centrosymmetric space group C2/c with cell constants of $a = 13.03$ Å, $b = 7.56$ Å, $c = 13.53$ Å, and $\beta = 140.87^\circ$. Each unit cell contains four molecules, with the anions centered on twofold rotation axes. The C—C bond distance is 1.43 Å.

5.1.4 Hexanitroethane

An extreme example in the series of polynitroethanes is hexanitroethane ($\text{NO}_2)_3\text{CC}(\text{NO}_2)_3$, $\text{C}_2\text{N}_6\text{O}_{12}$, CAS RN [918-37-6], molecular mass 300.0544 g/mol. It belongs to the group of nitrocarbons because it does not contain any hydrogen. It contains 63.98% oxygen. With an oxygen balance of +42.7%, it is a net oxidizer similar to tetranitromethane (TNM), because both compounds contain more oxygen than is necessary for complete combustion of carbon atoms to CO_2 .

Hexanitroethane is one of the few compounds that contain only a carbon skeleton and attached nitro groups. These compounds are called “nitrocarbons.” Other compounds with similar structures are TNM, hexanitrobenzene, octanitrocubane, or decanitrobiphenyl. There is even a book devoted exclusively to these types of chemicals, which make good oxidizers for rocket propellants [110].

5.1.4.1 Physical Properties of Hexanitroethane

Hexanitroethane is a compound of interest as a rocket propellant oxidizer due to its high oxygen content. It forms colorless crystals when crystallized from ether, is non-hygroscopic, slightly volatile at room temperature, explodes on rapid heating above 633 K (360 °C), and by the action of a detonator. It is soluble in diethyl ether, benzene, or chloroform, but only poorly soluble in ethanol and insoluble in water.

Hexanitroethane is a solid at room temperature, melts at 420 K (147 °C = 297 °F), and explodes when heated to near 448 K (175 °C). It readily sublimates and the vapors are very toxic. Good summaries of the physical and chemical properties of hexanitroethane have been published [111–113]. The physical properties of hexanitroethane are summarized in Table 13. Other properties were included in earlier tables showing the properties of nitroalkanes as a group.

The vapor pressure of hexanitroethane is listed in Table 14.

Table 13: Physical properties of hexanitroethane.

Property	SI units	Other units	Reference
Molecular mass	300.0544 g/mol	3.3327 mol/kg

358	85	2828	28	21.3

Data source: [2]

The vapor pressure of hexanitroethane can be calculated from the equation

$$\log P = 5.0244 - 1590/T$$

where P is the pressure in mm Hg and T is the temperature in kelvin [111].

Optical Properties of Hexanitroethane

The IR and Raman spectra of hexanitroethane in solution (Figure 1) confirmed the D_{3d} symmetry and staggered configuration of this molecule [114]. The D_{3d} symmetry was chosen as the more probable symmetry instead of the D_{3h} symmetry. The latter has an eclipsed structure, with the C—NO₂ plane perpendicular to the C—C axis. The vibrational fundamentals and a number of combination bands could be assigned and compared to similar assignments in two nitroethanes and four nitromethanes.

Figure 1: Infrared spectrum of hexanitroethane. (Republished and modified from [114], with permission of © 1974 Elsevier Science & Technology Journals; permission conveyed through Copyright Clearance Center Inc.)

Molecular Structure of Hexanitroethane

The crystal structure of hexanitroethane has been determined in the low-temperature ordered phase at 145 K and found to be space group $P2_1/c$ with $a = 10.152(2) \text{ \AA}$, $b = 9.311(2) \text{ \AA}$, $c = 10.251(2) \text{ \AA}$, $\beta = 97.54(1)^\circ$, $V = 960.6(3) \text{ \AA}^3$, $Z = 4$, with two non-equivalent molecules in the unit cell [115]. The far-IR, IR, and Raman spectra of hexanitroethane in both low-temperature ordered and high-temperature disordered crystal phases were recorded, and the internal modes of vibration were interpreted with the help of normal coordinate analysis and a conformational analysis with the MNDO method. This helped to explain the phase transition mechanism.

Three theoretical types of nitroform derivatives based on the hexanitroethane structure were designed by molecular modeling and their stability and explosive performance was predicted by computations [116]. It was hoped that such calculations would lead to the future development of more thermally stable nitro compounds.

Thermodynamic Properties of Hexanitroethane

The thermodynamic properties of hexanitroethane are summarized in Table 15.

Table 15: Thermodynamic properties of hexanitroethane

Property	SI units		Other units		References
Enthalpy of formation ΔH_f^{298}	+79.5 kJ/mol	+264.9 kJ/kg	+19.0 kcal/mol	+63.3 cal/g	[2]
Enthalpy of formation ΔH_f^{298}	+117 $\pm 8 \text{ kJ/mol}$	+390 $\pm 27 \text{ kJ/kg}$	+28 kcal/mol	+93 cal/g	[111]
Enthalpy of formation ΔH_f^{298}	+108 $\pm 4.2 \text{ kJ/mol}$	+360 $\pm 14 \text{ kJ/kg}$	+25.8 $\pm 1.0 \text{ kcal/mol}$	+86 $\pm 3.3 \text{ cal/g}$	[117]
Enthalpy of formation ΔH_f^{298}	+119 kJ/mol	+397 kJ/kg	+28.5 kcal/mol	+95 cal/g	[97]
Heat of sublimation	71 $\pm 2 \text{ kJ/mol}$	237 kJ/kg	16.97 kcal/mol	56 cal/g	[117]

Molecular mass 300.0544 g/mol, 3.333 mol/kg

The heat capacity of the crystalline phase I of hexanitroethane is $327 \text{ J mol}^{-1} \text{ K}^{-1}$ at 291 K [118]. Phase I exists from 190 to 350 K. See also [82].

5.1.4.2 Thermal Decomposition of Hexanitroethane

The rates of decomposition of hexanitroethane were determined in a number of solvents and as the pure solid in the temperature range of 333 to 373 K (60 to 100 °C) [119]. The products of reaction from the complete thermal decomposition of the solid can be

represented by the equation

The decomposition of hexanitroethane for the pure solid and in CCl_4 proceeds by a first-order reaction. The specific first-order rate constants are for solid hexanitroethane

$$k = 10^{18.6} \exp(-38900/RT) \text{ s}^{-1}$$

and for dissolved hexanitroethane in CCl_4

$$k = 10^{18.5} \exp(-37800/RT) \text{ s}^{-1}$$

The gas-phase decomposition of hexanitroethane has been studied over a temperature range of 373 to 433 K (100° to 160 °C) using a manometric method [120]. The reactions were found to be homogeneous and first order. The rates were independent of vapor pressures and of nitric oxide and nitrogen dioxide additions. The results were interpreted in terms of a radical non-chain mechanism, with C—N bond scission being the first step. The flash pyrolysis of hexanitroethane under vacuum forms tetranitroethylene, a very active Diels–Alder additions reagent [121].

5.1.4.3 Explosive Properties of Hexanitroethane

The friction sensitivity of hexanitroethane shows a reaction at a pistil load of 240 N. In the Trauzl lead block test, bulging of the cavity resulted in a volume increase of $245 \text{ cm}^3/10 \text{ g}$. Other sources describe the explosive power by Trauzl test as 115% of that of TNT. The detonation velocity of confined hexanitroethane is $4950 \text{ m/s} = 16240 \text{ ft/s}$ at $\rho = 0.91 \text{ g/cm}^3$. Mixtures of hexanitroethane and boron powder have been evaluated as chlorine-free igniters and explosives [122].

5.2 Polynitroethenes

While most of the work in the past has been on polynitroalkanes, the stabilizing effect of electron conjugation between electrons in the nitro group and electrons in the $\text{C}=\text{C}$ double bond has brought about a flurry of synthesis work with unsaturated nitro compounds [123].

5.2.1 1,1-Diamino-2,2-Dinitroethene

The predominant representative in the group of C_2 polynitroethenes is 1,1-diamino-2,2-dinitroethylene, also known as 1,1-diamino-2,2-dinitroethene, $(\text{H}_2\text{N})_2\text{C}=\text{C}(\text{NO}_2)_2$, $\text{C}_2\text{H}_4\text{N}_4\text{O}_4$, DADNE, DADE, FOX-7, CAS RN [145250-81-3]. It is a less-sensitive explosive,

which could find application as a substitute for RDX (less sensitive but with preservation of performance) in explosive as well as rocket propellant applications. It is a surprisingly simple molecule (compared to complex structures like hexanitrohexaazaisowurtzitane, CL-20), with a molecular mass of 148.07756 g/mol and an oxygen balance of -21.6%. It is not sure if FOX-7 itself will find application as a solid rocket propellant ingredient, but some of its derivatives are useful as energetic ingredients and listed here nevertheless.

1,1-Diamino-2,2-dinitroethylene, FOX-7, DADNE

Looking at the history of explosives development, it is surprising that FOX-7 was discovered only a few years ago and that people “stumbled” upon it while they were looking for other compounds.

1,1-Diamino-2,2-dinitroethene (DADNE, FOX-7), an insensitive energetic material, was first synthesized in 1998. It has since attracted the interest of the energetic materials research community for its high potential in diverse applications. FOX-7 was developed in Sweden by the Swedish Defense Research Agency (FOI) and its production was licensed to what is now EURENCO [124]. The first two letters of FOX are derived from the name of the agency (**FOI**) and the X stands for **eX**plosive. FOX-7 has roughly the same performance as RDX but is less sensitive. FOX-7 is a relatively new addition to the arsenal of rocket propellant ingredients and most of the information is scattered over recent publications. This area was still being actively investigated while the manuscript for this book was compiled. There is an on-going flood of publications on this material and new references pour in every month. An excellent summary of the properties of FOX-7, including 61 literature references, was published in 2007 [125]. See also [126–129].

New derivatives of FOX-7 and its hydrazine analogue 1-amino-1-hydrazino-2,2-dinitroethene as well as their potassium salts have been made [130]. Besides the usual spectroscopic characterization, the structures of all compounds were investigated by single-crystal XRD. The compounds demonstrated good thermal stabilities, very high densities, and favorable sensitivity values. The heats of formation were calculated, and together with the room-temperature densities, the detonation parameters were estimated.

5.2.1.1 Preparation of FOX-7

FOX-7 was first synthesized in 1998 [131]. The historically used method started with the condensation of acetamidinium chloride and diethyl oxalate:

FOX-7 can also be prepared by nitration of 4,6-dihydroxy-2-methylpyrimidine, which is commercially available [132]. The intermediate product is 2-dinitromethylene-5,5-dinitrodihydropyrimidine-4,6(1H,5H)-dione, which is hydrolyzed to form 1,1-diamino-2,2-dinitroethene in 90% yield along with dinitromethane as a by-product.

Low-temperature nitration of 2-methylimidazole gave intermediates which were aminated to form 1,1-diamino-2,2-dinitroethylene [133]. The synthesis route in the literature was scaled up and reaction conditions were optimized. The overall yield was 14.9% of the theoretical yield. The structure of FOX-7 was then characterized by IR spectroscopy, mass spectroscopy (MS), nuclear magnetic resonance (NMR), and elemental analysis.

FOX-7 was synthesized by amination of intermediates which were prepared by nitration of 2-methylimidazole [134]. 2-Methyl-4(5)-nitroimidazole and parabanic acid were separated from the filtrate of the intermediates. 2-Methyl-4(5)-nitroimidazole and parabanic acid were also synthesized by nitration of 2-methylimidazole under different conditions, with yields of 67.3 and 63.3%, respectively. An important step was rearrangement of the nitro group. FOX-7 was formed mainly by the following steps: 2-methylimidazole $\rightarrow$ 2-methyl-4,5-dihydro-imidazol-5-one $\rightarrow$

2-(dinitromethylene)-5,5-dinitro-4-imidazolidinone $\rightarrow$ 2-(dinitromethylene)-4(5)-imidazolidinedione $\rightarrow$ FOX-7.

Nitration of 2-methylimidazole gave intermediates which were aminated to form 1,1-diamino-2,2-dinitroethylene [135]. The synthesis route described in the literature was scaled up properly and reactive conditions were optimized. The yield of FOX-7 was 18.8%. The structure of FOX-7 was characterized by IR, MS, NMR, and elemental analysis.

Nitration of 2-methylimidazole at ambient temperature gave 2-(dinitromethylene)-5,5-dinitro-4-imidazolidinone, which reacted with water to give FOX-7 [136]. The key step was ring cleavage of 2-(dinitromethylene)-5,5-dinitro-4-imidazolidinone by addition of water to the reaction mixture or vice versa. By this method, the conversion of 2-methylimidazole to FOX-7 could be achieved in a continuous process. The overall yield was 35.8%.

Nitration of some 2-substituted-1,4,5,6-tetrahydro-pyrimidine-4,6-diones gave several new 2-substituted-1,4,5,6-tetrahydro-5,5-*gem*-dinitropyrimidine-4,6-diones in high yields (>80%) [137]. The *gem*-dinitro products formed were easily attacked by nucleophiles with the formation of *gem*-dinitroacetyl derivatives, which in turn could be further hydrolyzed to the salts of dinitromethane. When the substituent at position 2 was an alkyl group, nitration occurred both at position 5 and at the α -carbon atom of the side chain. If the alkyl group was methyl, the product would be 2-(dinitromethylene)-5,5-dinitropyrimidine-4,6-dione, which was hydrolyzed to form 1,1-diamino-2,2-dinitroethylene (FOX-7) and dinitromethane. Three different synthetic routes leading to FOX-7 were compared and the reaction mechanisms were discussed.

An improved synthetic route for FOX-7 was investigated by nitration of 2-methyl-4,6-pyrimidindione in nitric acid/sulfuric acid and hydrolysis of the intermediate 2-dinitromethylene-5,5-dinitro-dihydro-pyrimidine-4,6-dione with a total yield of over 83% [138]. The structure of FOX-7 made by this method was then characterized by IR, MS, NMR, and elemental analysis.

1,1-Diamino-2,2-dinitroethene (FOX-7) was synthesized with 2-methylpyrimidine-4,6-dione as feedstock by nitration and hydrolysis steps in turn. The yield was 85% [139, 140].

By way of a commercially used method, FOX-7 has been synthesized by treatment of acetamidinium chloride with diethylmalonate to obtain 2-methyl-pyrimidine-4,6-dione, which on nitration gives 2-dinitromethylene-5,5-dinitrodihydropyrimidine-4,6-dione, followed by hydrolysis to give FOX-7 [141]. It is currently used in pilot-scale production in batches up to 600 kg. The main disadvantage of this procedure is the handling of the intermediate 2-dinitromethylene-5,5-dinitrodihydropyrimidine-4,6-dione, which is sensitive to mechanical stimuli and chemically unstable. The by-product dinitromethane is formed at a rate of 0.7 kg for each kilogram of FOX-7, and there is not much of a market for it or its potassium salt.

The theoretically computed explosive and ballistic parameters were close to those of RDX. The synthesized FOX-7 has been used as a precursor for the synthesis of potassium and guanidinium salts and thermal analysis of these salts indicated their exothermic capabilities, making them suitable for incorporation in propellants.

After comparing three possible routes for synthesis, the improved 2-methyl-4,6-pyrimidine-dione method using 2-methyl-4,6-dihydroxy-pyrimidine as raw material was recommended as a good method to produce FOX-7 [142, 143].

An improved process for the preparation of 1,1-diamino-2,2-dinitroethene suitable for scale-up was developed which involved the synthesis of 2-methoxy-2-methylimidazolidine-4,5-dione and its conversion into 2-hydroxy-2-methylimidazolidine-4,5-dione, which is a new intermediate in the synthesis of 1,1-diamino-2,2-dinitroethene [144]. Its nitration produced 2-(dinitromethylidene)-imidazolidine-4,5-dione, whose hydrolysis into 1,1-diamino-2,2-dinitroethene was further improved. The starting reactant acetamidinium chloride was switched to acetamidinium acetate. It is possible to carry this out as a one-pot synthesis without isolation of acetamidinium acetate. The new procedure yields no hazardous by-products or intermediates such as dinitromethane or 2-(dinitromethylidene)-5,5-dinitrodihydropyrimidine-4,6(1H,5H)-dione or methyl nitrate. Thus, the process safety was enhanced in

comparison to the commercial production process starting from 2-methylpyrimidine-4,6-dione.

Nitration reactions are exothermic and improper heat management can result in runaway reactions and explosions. Thermochemistry data such as heat flow curve vs. time, heat transfer coefficient, and heat capacity in the nitration reaction of 2-methylpyrimidine-4,6-dione for the synthesis of 1,1-diamino-2,2-dinitroethylene (FOX-7) were measured in a reaction calorimeter [145]. Results showed that the average heat release rate of nitration reaction during feeding of reactants was about 80 W and in the finishing period about 40 W (depending on the size of the reactor). The total exothermic heat of nitration reaction was 375 kJ/mol, and the adiabatic temperature rise can go as high as 483 K. The thermal stability of the intermediate 2-dinitromethylene-5,5-dinitropyrimidine-4,6-dione was analyzed by differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA). Results showed that its thermal decomposition process can be divided into two stages: the initial decomposition started at 303 K (30 °C), the peak temperature of the first-stage decomposition was 340 K (67 °C), and the enthalpy of the decomposition reaction was 201 J/g; the peak temperature of the second stage was 360 K (87 °C) and the enthalpy of the decomposition reaction was 1047 J/g. This indicated that the thermal stability of the 2-dinitromethylene-5,5-dinitropyrimidine-4,6-dione intermediate is very poor.

The optimum conditions for the synthesis of FOX-7 were determined, this time not experimentally in a test tube, but theoretically by computer, simulating the established route from 2-methylimidazole via oxidation followed by nitration and aminolysis [146]. Possible variations that were distinct from those reported in the literature were simulated, including the use of a solvated oxidative reaction system, the replacement of nitrating agent HNO_3 by N_2O_5 , and the adoption of cupric oxide or ferrous oxide catalysts for aminolysis. The calculations suggested that water is a good medium for the oxidation reaction, N_2O_5 is a better agent for nitration, and iron(II) oxide would be a suitable catalyst for aminolysis in hydrated systems. See also [147, 148].

5.2.1.2 Recrystallization of FOX-7

FOX-7 as obtained from most synthesis methods is not usable in many propellant formulations since the particle size is much too small or the particle size range and shape are too irregular. Therefore, FOX-7 may have to be recrystallized in a mixture of *N*-methylpyrrolidin-2-one and water or dimethyl sulfoxide and water or dilute hydrochloric acid (HCl) [149, 150] or ethanol [151]. The crystal shape depends on the type of solvent used. Cubic-shaped particles with a rather broad size distribution (approximately 30–800 μm) can be obtained (Figure 2).

In order to understand the influence of FOX-7 crystal shape and size on its thermal properties, FOX-7 crystals were obtained from the solvent systems dimethylformamide (DMF)/ H_2O and *N*-methyl-2-pyrrolidone (NMP)/ H_2O by cooling crystallization and also by anti-solvent crystallization [153, 154]. Scanning electron microscope (SEM) examination showed that the obtained crystals had two shapes, namely extended tetra-

Figure 2: Crystal shapes of recrystallized FOX-7. (From [152].)

hedral or hexahedral prism and rhombohedral prismatic crystals. The crystal shape can be controlled by ultrasonic treatment. The shape of crystals obtained by ultrasonic treatment was more uniform, but the crystals' surface was comparatively rough. DSC results showed that the thermal properties of FOX-7 obtained by different means and different solvent systems were different. This indicated that FOX-7 crystals with different shapes, sizes, and thermal properties can be obtained by crystallization in different manners and solvent systems.

In order to obtain a fine-grain product, FOX-7 was dissolved in NMP while boiling. The solution was poured into water at ambient temperature and the suspension was vigorously stirred. After filtering, the product was slowly dried in an air atmosphere. A fine-grain product of quite regular shapes was obtained by this method [155, 156]. Spherical particles of FOX-7 can be prepared using a microemulsion technique [157].

5.2.1.3 Physical Properties of FOX-7

FOX-7 forms yellow crystals that can crystallize into two polymorphic forms as either α phase or β phase. The molecular mass is 148.08 g/mol. The oxygen balance is -21.61% and it is thus under-oxidized, similar to RDX. A thorough investigation of as-received samples from two different suppliers and recrystallized samples was done by van der Heijden et al. [158, 159]. The materials were characterized by XRD, SEM, pycnometry, differential thermal analysis (DTA)/TGA, DSC, high-performance liquid chromatography (HPLC)/MS, vacuum stability, impact sensitivity, and electrostatic discharge (ESD) sensitivity. See also [160, 161].

Melting Point of FOX-7

The melting point of FOX-7 is 543 K (270 °C) with beginning decomposition.

Phase Changes of FOX-7

FOX-7 crystallizes in at least three different polymorphic forms: α -FOX-7, β -FOX-7, and γ -FOX-7. The α modification converts reversibly to the β form at 389 K. At 435 K the β polymorph undergoes a transition to the γ polymorph and this conversion is irreversible. FOX-7 has several other phases which form on heating the normal α -polymorph and can be identified by DSC. The first phase transition ($\alpha \leftrightarrow \beta$) occurs at 386 K (113 °C), has an endothermic peak of 18 J/g, and is completely reversible. The β polymorph has an orthorhombic crystal structure. The second phase transition ($\beta \rightarrow \gamma$) occurs at 446 K = 173 °C and is only partially reversible. Above 473 K (200 °C) the explosive begins to decompose. The phase-change behavior of FOX-7 crystals depends on the solvent from which they were crystallized.

Phase changes of FOX-7 at pressures up to 10 GPa through isothermal compression at 373 and 473 K (100 and 200 °C) have been studied using synchrotron mid- and far-IR spectroscopy [162]. During isothermal compression at 373 K (100 °C), changes were observed in vibrational spectra with an increase in pressure that were indicative of significant distortion to a monoclinic α phase or a possible structural transformation to a high pressure α' phase at 2.2 GPa and α'' phase at 6.1 GPa. There was no evidence of sample decomposition over the total P - T range investigated, up to ~10 GPa and 473 K (200 °C). The observed changes were partially reversible, with only slight evidence of the high pressure distortion remaining upon complete decompression.

Density of FOX-7

The pycnometric density of FOX-7 at 298 K is 1.885 g/cm³. This density is higher than that of RDX (RDX: 1.82 g/cm³), making FOX-7 a potential candidate for replacement of RDX and the higher density partially compensates for its lower explosive output. The X-ray density is 1.907 g/cm³. The $\alpha \rightarrow \beta$ transition is accompanied by a density decrease of 1.9%. This might cause debonding of FOX-7 crystals embedded in a binder matrix. Density: α polymorph 1.89 g/cm³; β polymorph 1.80 g/cm³.

The density of as-received FOX-7 from two different suppliers was 1.86 and 1.877–1.879 g/cm³, respectively [158, 159]. Other sources reported the crystal density as 1.88 g/cm³ [141].

Optical Properties of FOX-7

The FOX-7 ultraviolet spectrum (in water) exhibits three maxima at 210, 278, and 346 nm. The UV spectrum of FOX-7 vapor indicated a strong band at 216 nm (for a normal carbon–carbon double bond one would expect 165 nm) for a $\pi \rightarrow \pi^*$ transition which corresponds to an ethylene carbon–carbon double bond. The higher value (216 nm as opposed to 165 nm) indicated that the presence of extensive π - π conjugation in the molecule and a stronger band at 279 nm for $n \rightarrow \pi^*$ transition are

due to the presence of nitro groups. The IR spectrum of FOX-7 revealed the presence of primary amino groups at 3408, 3330, and 1636 cm^{-1} and nitro groups at 1520 and 1472 cm^{-1} .

The IR spectrum of solid FOX-7 in KBr pellets showed absorption bands at 3417 (NH_2), 3315 (NH_2), 3200 (NH_2), 1638 (NH_2), 1524 (NO_2), 1471, 1400, 1356 (NO_2), 1234, 1176, 1143, 1027, 752, 652, 521, and 462 cm^{-1} [125].

Raman spectroscopy was used for a temperature-dependent study of the phase transitions of FOX-7, where the N—H band at 3332 cm^{-1} (marked with an asterisk) showed an increase in intensity just before the phase transition, followed by a decrease in intensity (Figure 3).

Figure 3: Raman spectra of FOX-7 representing progressive heating at (a) 50, (b) 75, (c) 100, and (d) 105 °C (Reprinted and modified from [163], with permission from © 2007 American Chemical Society.). The band at 3332 cm^{-1} marked with an asterisk is due to N—H. bonds

This change indicated a reorganization of the H-bonding in crystalline FOX-7, leading to stabilization of a different form of FOX-7. Figure 3 presents the Raman spectra of pure FOX-7 subjected to progressive heating, which clearly shows a transition from the α phase to the β phase.

Raman spectroscopy was used to examine the vibrational and polymorphic behavior of 1,1-diamino-2,2-dinitroethene and to elucidate its structural and chemical stability under high pressure [164–166]. Measurements were performed on single crystals compressed in a diamond anvil cell, and data were obtained over the entire frequency range of FOX-7 Raman activity. Several new features were observed with an increase of pressure: (i) new vibrational peaks and discontinuity in the shifts of the peaks at 2 and 4.5 GPa; (ii) apparent coupling or mixing of several modes; and (iii) changes in the NH_2 stretching spectral shape and modes shift. A large pressure

hysteresis regarding the changes at 4.5 GPa implied a reconstructive transformation. FOX-7 has remarkable chemical stability under high pressure.

Solubility of FOX-7

FOX-7 is insoluble in cold water and slightly soluble in acetonitrile and cyclohexanone. FOX-7 is only slightly soluble in common organic solvents and water, but readily dissolves in polar aprotic solvents such as dimethyl sulfoxide, *N,N*-dimethyl formamide, or 1-methyl-2-pyrrolidinone. The solubility of FOX-7 in common solvents is summarized in Table 16.

Table 16: Solubility data for DADNE-FOX-7.

Solvent	Solubility, g/100 mL at 293 K = 20 °C
Acetone, acetic acid, <i>n</i> -butanol	<0.1
Ethyl acetate, nitromethane, water	<0.1
Acetonitrile	<0.5
Cyclohexanone	<0.5
Dimethylformamide	21
<i>N</i> -Methylpyrrolidone	32
Dimethyl sulfoxide	Approximately 45

Data source: [126]

Thermodynamic Properties of FOX-7

Throughout this chapter the properties of FOX-7 have been repeatedly compared to those of RDX, which it may potentially replace. The enthalpy of formation of FOX-7 is negative, while that of RDX is positive. There are varying results for the enthalpy of formation of FOX-7, ranging from −53 to −133.9 kJ/mol or −134 kJ/mol, depending on which source you trust. This requires additional work to eliminate unreliable data. An enthalpy of formation of −130 kJ/mol appears to be a reliable number. In comparison, the enthalpy of formation of RDX is +92.6 kJ/mol (other authors list +67 kJ/mol).

The calculated heat of explosion according to the equation

is −574 kJ/mol = −3.88 MJ/kg = −7.29 MJ/L, which is half of that of RDX on a per-mol basis. For RDX the heat of explosion is −1123 kJ/mol = −5.06 MJ/kg = −9.21 MJ/L. On a volume basis, FOX-7 output is only 21% less than of that of RDX.

The standard molar heat capacity of FOX-7 was determined with two continuous heat capacity at constant pressure C_p modes of operation of a microcalorimeter to be 176.56 and 176.02 J mol^{−1} K^{−1} at 298.15 K, respectively [167]. The relative deviation between these two results was 0.31%. The heat capacity of FOX-7 was also calculated by a DFT method, and the relative deviation between theoretical calculation and experi-

mental determination ranged from 13.27 to 15.46% within the range of 283–353 K. Using the above determination results of heat capacity, thermodynamic functions of FOX-7 relative to the standard temperature 298.15 K were calculated through thermodynamic relationships, and predicted adiabatic time-to-explosion was also calculated.

The heats of combustion of FOX-7 and five of its closed-loop derivatives were determined and the standard molar enthalpies of formation were calculated [168]. The heats of combustion for the six compounds decreased in the order 2-(dinitromethylene)-1,3-diazacycloheptane > 4-methyl-2-(dinitromethylene)-1,3-diazacyclopentane > 2-(dinitromethylene)-1,3-diazacyclohexane > 2-(dinitromethylene)-1,3-diazacyclopentane > 4,5-dihydroxyl-2-(dinitromethylene)imidazolidine > FOX-7. The heat of combustion increased with an increase in the number of C atoms in the molecule. The standard molar heat capacities of the six compounds were 176.59, 205.41, 207.76, 218.89, 217.76, and 215.40 J mol⁻¹ K⁻¹, respectively. The specific heat capacities changed with the number of C atoms in an opposite direction from the heat of combustion. The introduction of hydroxyl groups can markedly decrease the heat of combustion and specific heat capacity.

Gas-phase enthalpies of formation for 3-nitro-1,2,4-triazol-5-one (NTO), FOX-7, LLM-105, TNT, RDX, 1,3,5-triamino-2,4,6-trinitrobenzene (TATB), HMX and PETN were calculated using quantum composite methods [169]. Results from some calculations were close to one another, with a larger difference found between other methods. The mean absolute deviations between average experimental values and calculations were 12 to 3 kcal/mol.

Molecular Structure of FOX-7

The molecular structure of FOX-7 possesses bond lengths and angles that are typical for a so-called push–pull alkene, which is an alkene with groups of greatly differing electron affinity at either end. The C=C bond length is 1.456 Å, intermediately between that of a C–C single bond (1.54 Å) and that of a normal C=C bond (1.34 Å). The C–NH₂ and C–NO₂ bonds are shorter than in alkylamines or nitroalkanes.

It has been suggested that the low drop-weight and low friction sensitivity of FOX-7 (compared to that of RDX) is due to the crystal structure. FOX-7 forms yellow/orange crystals which crystallize in the monoclinic form (α phase). The crystals have a graphite-like structure with parallel planes, similar to that of TATB, which allows for internal flexibility. The layers are held together by strong hydrogen bonds [170]. The distance between layers is 3 Å.

Eight amino and/or nitro derivatives of ethene have been investigated computationally by a density functional theory method [171]. The molecular geometries and relative stabilities reflect the varying roles of push–pull electron delocalization and intramolecular hydrogen bonding in compounds like 1,1-diamino-2,2-dinitroethylene. The same two factors affect, to varying extents, the computed C–NO₂ and C–NH₂ bond dissociation energies and the heats of formation, vaporization, and sublimation of the diaminodinitroethylenes.

The effects of pressure on the structural and vibrational properties of the layered molecular crystal of FOX-7 were explored by first principles calculations [172]. Using density functional theory (DFT) methods, significant changes in the calculated structural properties with different corrections for treating van der Waals interactions were observed. In particular, the calculated ground-state lattice parameters, volume, and bulk modulus were found to agree well with experiments. The calculated vibrational frequencies demonstrate the dependence of the intra- and inter-molecular interactions on FOX-7 under pressure.

Crystal Structure of FOX-7

It has been attempted to calculate the equation of state and predict structural changes in FOX-7 from experimental studies and *ab initio* quantum calculations [173].

Molecular computer simulation can be used to calculate energies of molecular systems. There are basically two methods: quantum mechanical calculations and force fields methods. Quantum mechanical calculations give accurate results and can also be used to calculate chemical reactions, but consume a lot of computer time, especially for systems containing several molecules. Force fields methods can describe molecular systems by means of simple mechanical models. Energy terms for bonds, bond angles, torsions, van der Waals-interactions, and electrostatic interactions are available. In comparison to quantum mechanical calculations, the simulation computing time is quite short. A force field method was used to predict the shape of FOX-7 crystals, which depends on the growth rates of the crystal faces during the crystallization process and on the interaction energies of the faces and the solvent molecules [174, 175].

The structure of FOX-7 has been identified by elemental analysis, IR, MS, and NMR [176]. The single crystal of FOX-7 was cultivated from acetonitrile. Its crystal structure was determined by XRD with a single crystal. The results showed that the crystal belongs to a monoclinic system, space group $P2_1/n$, with crystal parameters of $a = 0.6930(14)$ nm, $b = 0.6630(13)$ nm, $c = 1.1360(2)$ nm, $\beta = 90.43(3)^\circ$, $V = 0.5219(18)$ nm³, $Z = 4$, and $D_c = 1.885$ g/cm³.

XRD is the preferred tool for investigation of the crystal structure of energetic materials. XRD has revealed a monoclinic structure of FOX-7 with $a = 6.941$ Å, $b = 6.569$ Å, $c = 11.315$ Å, $\beta = 90.55^\circ$, $V = 515.9$ Å³, $D_x = 1.907$ g/cm³, and $Z = 4$. Whereas positions and intensities of diffraction peaks yield information on the crystal structure, peak profiles (e.g., width at half-height) are related to the real structure determined by crystallite sizes, shapes, and micro-strains. The size/strain broadening of FOX-7 XRD peaks was measured and interpreted based on crystal geometry [177]. The investigations correlated the size/strain broadening with particle processing history and mechanical sensitivities. Compressibility can be different in different axes of the crystal. Shock loading may result in rapid compression in one axis but not in the other, leading to hotspots and accidental ignition of energetic materials. Anisotropic diffraction-peak broadening was found for some of the energetic

materials. Micro-strains are left behind after grinding the materials or as the result of imperfect (hastened) crystal growth. The size/strain broadening of FOX-7 XRD peaks was measured and interpreted based on crystal geometry, contaminants and internal crystal defects, also in comparison to similar measurements on RDX and ammonium dinitramide (ADN). The molecular layer structure is reported to be a model for low-sensitivity materials, such as FOX-7 or TATB. In this model the principal mechanism for release of mechanical load is layer slippage (as in graphite), which retains the internal layer structure undisturbed.

The supersaturation-dependent growth habit of FOX-7 crystals was accurately predicted by step energy calculation and simulations [178]. The rod-like shape of FOX-7 originates from the slowest growth rate of the {111} face because of a large energy barrier of nucleation and a low sticking fraction relative to other faces at low supersaturation. The anisotropic growth habit of crystal faces diminished as the supersaturation increased.

5.2.1.4 Chemical Properties of FOX-7

Due to the strong polarization of the C=C double bond, FOX-7 can undergo a wide variety of reactions, such as transamination and hydrolysis reactions.

Reactions of FOX-7

FOX-7 is quite reactive and can undergo a multitude of reactions like cycloadditions, nitration, halogenation, and acylation [179]. FOX-7 can give unexpected products as a result of its specific reactivity [180]. The structures of the new compounds were identified by XRD. The nucleophilic *gem*-dinitrocarbon of FOX-7 seemed to be directly involved in these transformations.

In reactions with amines, FOX-7 behaves as an electrophile via 1,4 conjugate addition. Although reactions with simple alkyl amines often yield unresolved mixtures of mono- and bis- substituted addition products, reactions with diamines yield cyclic amines in good yield and purity. Conversely, FOX-7 behaves as a nucleophile in amine alkylation and acylation reactions, albeit a poor one. FOX-7 is roughly 25 orders of magnitude less basic than simple alkyl amines ($pK_a = 10.6$). FOX-7 is such a poor nucleophile that *N*-alkylation and *N*-acylation require refluxing conditions.

Amphoteric Behavior of FOX-7

FOX-7 is an acid ($pK_a = 10.6$) and after loss of a proton the anion assumes the structure of an imine $(H_2N)HN=C-C^-(NO_2)_2$. Salts are formed with guanidine or potassium hydroxide. Hydrolysis leads to the potassium salt of dinitromethane.

On the basis of liquid and solid-state ^{13}C and ^{15}N NMR data, XRD analysis, and *ab initio* calculations, it was suggested that 1,1-diamino-2,2-dinitroethylenes are always zwitterionic and that the C=C bond is not a true double bond [181].

1,1-diamino-2,2-dinitroethene and its hydrazine derivative, 1-amino-1-hydrazino-2,2-dinitroethene (HFOX), form cations with strong acids such as triflic, perchloric,

and hydrochloric acid [182]. The following salts were prepared and characterized: 1-amino-2,2-dinitroethaniminium triflate, 1-amino-2,2-dinitroethaniminium perchlorate, 1-amino-1-hydrazino-2,2-dinitroethaniminium triflate, and 1-amino-1-hydrazino-2,2-dinitroethaniminium chloride. These compounds had thermal stabilities ranging between 347 and 420 K (74 and 147 °C) and crystal densities between 1.53 and 1.94 g/cm³. The isolation of these FOX-7 and HFOX cations extended the chemistry of FOX-7 and HFOX and demonstrated the amphoteric properties of FOX-7 and HFOX. All the salts were found to have energetic properties that exceeded those of TNT, and some were comparable to FOX-7 and RDX.

Salts of FOX-7

The reaction of 1,1-diamino-2,2-dinitroethene with KOH at room temperature forms the potassium salt of 1,1-diamino-2,2-dinitroethene, which on heating to 353 K (80 °C) decomposed to form the potassium salt of dinitromethane. Adding both KOH and guanidinium chloride to 1,1-diamino-2,2-dinitroethene formed the guanidinium salt of 1,1-diamino-2,2-dinitroethene in the form of yellow crystals, which was not more stable than the potassium salt and showed a more complex decomposition pattern in DSC with three peaks. It was more friction and impact sensitive than FOX-7 itself. Cesium, rubidium, cadmium, zinc, and copper complex salts containing FOX-7 have been reported.

It was attempted to increase the acidity and energy content of FOX-7 by converting the two amino groups into two nitramino groups and then stabilizing the compound as the diammonium salt, which would be called diammonium di(nitramido) dinitroethylene (ADNDNE).

The remaining hydrogens on the two amino groups would be more acidic than those in FOX-7 without nitramino groups. However, in spite of trying seven different synthesis routes, the ADNDNE salt was not obtained [183]. The salt was predicted to have a density of 1.77 g/cm³ and an enthalpy of formation of +16.8 kJ/mol (+4.02 kcal/mol). It seems highly premature to start worrying about possible environmental impacts of a chemical that is so unstable that it cannot even be obtained in milligram quantities in the laboratory. The computational methods used for predicting toxicity and environmental impact look very nice, but are, in reality, useless.

Halogenated FOX-7

Halogenated 1,1-diamino-2,2-dinitroethene compounds display hypergolic properties with common hydrazine-based fuels and primary aliphatic amines (ignition delay times of 2–53 ms) [184]. These compounds were characterized by single-crystal XRD, elemental analysis, IR spectra, and DSC.

5.2.1.5 Thermal Stability of 1,1-Diamino-2,2-dinitroethene (FOX-7)

Thermal Stability of 1,1-Diamino-2,2-Dinitroethene (FOX-7) – Experimental Studies

If FOX-7 is heated to above 473 K (200 °C) it begins to decompose without melting. DSC exotherms show up in the area around 513 K (240 °C) and decomposition is complete by the time the sample reaches 573 K (300 °C). Occluded solvents may change the location, the number, and the shape of DSC peaks. The DSC thermogram of FOX-7 showed two decomposition steps with peak maxima at 513 K (240 °C; $\Delta = -473$ J/g) and 552 K (279 °C; $\Delta = -542$ J/g).

Raw FOX-7 does not give thermograms with good reproducibility. They usually have a weak endotherm, with the peak moving from 368 to 383 K (95 to 110 °C), depending on the history of the product, and three exotherms: two weak ones at 473 and 518 K (200 and 245 °C), and a very strong one with the peak position at around 543 K (270 °C). However, recrystallized or reprecipitated products, independent of the type of solvent used, are characterized by two nicely reproducible endotherms – a pronounced one at 391 K (118 °C) and a weak one at ~438 K (~165 °C) – and two exotherms – a broad one with a peak at 518 K (245 °C) and a sharp one with a peak at 548–553 K (275–280 °C). The averaged kinetic parameters characterizing the decomposition process of FOX-7 are

$$E_a = 338.8 \text{ kJ mol}^{-1} \quad A = 1.266 \times 10^{38} \text{ s}^{-1} \quad n = 0.7$$

The DSC thermogram of FOX-7 showed a complex structure with two exothermic peaks, one at 511 K (238 °C) and another at 554 K (281 °C) [152]. From tests at varying heating rates, the activation energy for FOX-7 was measured to be 234 kJ/mol (56 kcal/mol), which, when compared to RDX (167 kJ/mol = 40 kcal/mol) and HMX (146 kJ/mol = 35 kcal/mol), shows that FOX-7 is more thermally stable than RDX or HMX. The TGA curve showed at least two, possibly four steps of weight loss. This indicated that a two-step decomposition dominates the initial decomposition of FOX-7, where the initial intermediate has a low thermal stability. The number of steps in the TGA curve can possibly explain the two peaks in the DSC thermogram. The analysis of thermal decomposition products was initially done on a conventional magnetic sector mass spectrometer and later extended to a time-of-flight (TOF) mass spectrometer with laser pyrolysis. A significant observation was that with a low electron impact ionization of 70 eV, FOX-7 exhibited a very strong molecular peak at a mass-to-charge ratio m/e equal to 148. This indicated that the molecule is very stable in the vapor phase compared to RDX and HMX. Earlier work had shown that NTO and TNT can have small molecular peaks at 70 eV.

The thermal decomposition of FOX-7 under isothermal conditions at constant volume showed a saturating character of gas evolution curves at a very low extent of decomposition [185]. The rate of gas evolution was characterized by an extremely high activation energy value, 385 kJ/mol (92 kcal/mol). Experiments conducted in an open vessel resulted in a significantly lower activation energy, i.e., 198 kJ/mol (47.4 kcal/mol). The reaction products hinder rather than accelerate further decomposition of FOX-7.

FOX-7 is usually transported suspended in water to prevent accidental explosions. In order to check any influence of the presence of water on the thermal stability properties of FOX-7, both wet and dry samples were tested by DSC [186]. By applying different heating rates, an analysis of the decomposition kinetics could be performed, which gives additional information on the activation energy of the decomposition process and the predicted shelf life of the material when stored at above normal temperature.

As a consequence of the extremely high values of the activation energy, FOX-7 is a very stable high explosive even at elevated temperatures. Kinetics of the two-step decomposition of FOX-7 were modelled using dynamic and isothermal DTA/TGA measurements [187]. The reaction product remaining after the first decomposition step (corresponding to about 38% mass loss) was investigated by NMR, XRD, IR, and HPLC. Surprisingly, all methods identified the intermediate solid reaction product as the initial compound FOX-7. The compound decomposing in the first step was assumed to be a less stable, amorphous fraction of FOX-7.

The whole process of thermal decomposition of FOX-7 was investigated by thermolysis with *in situ* cell rapid-scan IR [188, 189]. The activation energies for rupture of C—N, —NO₂, and C—NH bonds were obtained by a thermo-IR isothermal kinetic method: 181.7, 235.8, and 170.7 kJ/mol. The thermal decomposition process of FOX-7 is a two-step process. In the first step, hydrogen bond dissociation and isomerization of the —NO₂ group occur and some NO is released. The second step concludes the dissociation of the main bonds of FOX-7 and, at the same time, HCN and NH₃ are released.

The constant-volume combustion energy, ΔU_{comb} , the thermal behavior, and kinetics and mechanism of the exothermic decomposition reaction of FOX-7 were investigated by a rotating bomb calorimeter, thermal gravimetric analysis-differential thermal gravimetry (TGA-DTG), DSC, rapid-scan FTIR spectroscopy and T-jump/FTIR [190]. The value of ΔH_{comb} was determined as -8518.09 ± 4.59 J/g. Its standard energy of combustion, ΔU_{comb} , and standard enthalpy of formation, $\Delta H_f^{298.15}$, were calculated to be -1254 ± 0.68 and -103.98 ± 0.73 kJ/mol, respectively. The kinetic parameters (the apparent activation energy E_a and pre-exponential factor A) of the first exothermic decomposition reaction in a temperature-programmed mode obtained by Kissinger's method and Ozawa's method were $E_a = 344.35$ kJ/mol, $A_k = 10^{34.50} \text{ s}^{-1}$, and $E_o = 335.32$ kJ/mol. The critical temperature of thermal explosion of DADE was 480 K (207 °C).

The thermal decomposition mechanism of FOX-7 was studied by DSC and TG-DTG techniques [191]. The thermal decomposition of FOX-7 consisted of one endothermic

and two exothermic decomposition processes continuously. The TGA curve consisted of two-stage mass-loss processes. The endothermic peak was attributed to the crystal transformation and the exothermic peaks were due to the decomposition reaction of FOX-7 and its decomposition products.

The thermal decomposition behavior of FOX-7 was measured by DSC and TGA and by *in situ* thermolysis or fast thermolysis with rapid-scan Fourier transform IR spectroscopy and mass spectroscopy [192]. The results showed that there was a phase transition (β -phase to γ -phase) at 392 K (119 °C), and that the gas products of FOX-7 decomposition consisted of CO₂, CO, NO₂, NO, N₂O, HCN, and HNCO, of which CO₂, NO, N₂O, and HCN presented themselves in both the first and second stages of FOX-7 decomposition, whereas CO, NO₂, and HNCO were only evolved by the second-stage process.

In DSC, the endotherms and exotherms of as-received, dried FOX-7 were measured at heating rates of 2, 5, and 10 °C/min [158, 159]. For a heating rate of 2 °C/min there were three endotherms starting at 99.1, 112.8, and 171.0 °C, and two exotherms starting at 202.3 and 240.8 °C. The endotherms are associated with phase changes. On some samples, repeated DSC heating and cooling cycles were recorded to see if the decomposition products change the melting and decomposition behavior and whether all peaks appeared repeatedly in each cycle. The compatibility of FOX-7 with other energetic materials, binders, and curing agents was determined by vacuum stability measurements. Both glycidyl azide polymer (GAP) and hydroxyl terminated polybutadiene (HTPB) are compatible with FOX-7, and FOX-7 can be used as a replacement for RDX in nitramine propellants or plastic bonded explosive (PBX) formulations.

In addition to thermal stability studies of FOX-7 by itself, additional experiments were done with salts derived from FOX-7. It was hoped that some of the salts would have better properties than the parent acid itself. The guanidinium salt of 1,1-diamino-2,2-dinitroethene was prepared by mixing FOX-7 and guanidinium chloride solution in potassium hydroxide solution. Its thermal decomposition was studied under the non-isothermal conditions with DSC and TG/DTG methods [193] and its structure was determined by XRD [194]. The crystals belong to an orthorhombic system with space group Pbca and have a density of $\rho = 1.622 \text{ g/cm}^3$.

The thermal decomposition process of FOX-7 was investigated by using *in situ* FTIR, thermolysis GC/MS and DSC-TG [195]. The thermal decomposition mechanism of FOX-7 was studied through determining the gaseous products and structural changes of the condensed phase during heating. The results showed that the thermal decomposition of FOX-7 proceeds in two stages. In the first stage, the phase transition of FOX-7 is followed by an inter-molecular condensation reaction and NO is released from FOX-7 through nitro–nitrite rearrangement. Subsequently, FOX-7 is further decomposed into small molecule fragments.

Sensitivities of FOX-7 and HTPB propellants with FOX-7 were studied by means of DSC-TGA and various sensitivity test methods [196]. Results showed that the apparent activation energy of thermal decomposition of FOX-7 was 245.2 kJ/mol and the major exothermic DSC peak temperature occurred at 495 K (222 °C). Friction sensitiv-

ity was less than 68%, while impact sensitivity was over 25 J. Mechanical sensitivities and electrostatic discharge sensitivity of HTPB propellants with FOX-7 were more benign when compared to similar RDX formulations. When the content of FOX-7 in an AP/FOX-7/HTPB propellant is 15%, the violent exothermic decomposition of ammonium perchlorate (AP) is weakened and the major exothermic DSC peak occurs at about 533 K (260 °C), which is 40° lower than that of all-RDX/HTPB formulations.

The thermal decomposition process of FOX-7 was investigated by DSC, TGA, and T-jump rapid-scan FTIR coupling techniques [197]. Results showed that isomerization of the $-\text{NO}_2$ group occurs and NO is released, whereafter the decomposition of the main framework of FOX-7 liberates HNCO, HCN, NH_3 , CO_2 , CO, etc. The activation energy E_a was 247 kJ/mol, the decadic logarithm of the pre-exponential factor was 23.81. The reaction order of the early-stage pyrolysis mechanism of FOX-7 was 1.5.

Quantum mechanical computational methods were used to calculate the energy of the decomposition species of FOX-7 [198]. Based on the energy levels obtained by such methods, the rate constants of C– NO_2 cleavage and nitro-to-nitrite rearrangement were calculated in the temperature range of 250–3300 K. It was found that C– NO_2 cleavage would be the dominant initial thermal decomposition step at high temperature, which is consistent with the conclusion based on *ab initio* molecular dynamics simulations. The effects of NO_2 gas on FOX-7 decomposition were predicted. Results showed that the decomposition energy barrier became lower when NO_2 reacted with FOX-7.

The decomposition of FOX-7 was further investigated both theoretically and experimentally [199]. The NO molecule was observed as an initial decomposition product subsequent to electronic excitation. The observed NO product is rotationally cold (<35 K) and vibrationally hot (2800 K). The initial decomposition mechanism was computed by a theoretical method. Potential energy surface calculations illustrated that conical intersections play an essential role in the decomposition mechanism. When FOX-7 decomposes while it exists in the ground electronic state, the vibrational energy of the NO product from FOX-7 is high. The observed rotational energy distribution for NO is consistent with the final transition state structure on the S_0 state.

The ReaxFF molecular dynamics method was used in an investigation of the thermal decomposition mechanisms of FOX-7 and the results were compared to those obtained experimentally using a combination of TGA with online photoionization time-of-flight mass spectrometry (TG-PI-TOF-MS) and online single-photon ionization time-of-flight mass spectrometry (SPI-TOF-MS) [200, 201]. The results of the molecular dynamics simulations showed that the primary decomposition step of FOX-7 is C– NO_2 cleavage; after this, C=O formation occurs via a three-membered ring transition state, followed by NO elimination. The remaining structure loses NH_2 and H, resulting in formation of the $\text{NHC}=\text{C}=\text{O}$ structure, which finally breaks down into HNC and CO. NH_2 reacts with an H atom to produce NH_3 . During the decomposition of FOX-7, the major products are N_2 , NH_3 , CO_2 , and H_2N_2 , and the minor products are H_2O , HN_2 , and H_2 .

Thermal Stability of FOX-7 – Theoretical/Computational Studies

Computational chemistry electron density calculations have attempted to predict the decomposition path for FOX-7 [202]. The thermal decomposition behavior of FOX-7 at high temperature has been simulated using constant-temperature molecular dynamics and density functional theory methods [203]. It was found that most of the energy is released within the first 15 ps of the reaction. The main products are N_2 and H_2O molecules, and their populations generally increase with time. Some charged groups (like NO_2^+ and OH^-), which are observed in the initial stage of decomposition, may promote further reaction.

Ab initio molecular dynamics simulations were conducted to study the thermal decomposition mechanisms of solid FOX-7 [204]. It was found that the initial decomposition of FOX-7 has three main reaction routes and that C– NO_2 bond fission, as reported previously, is indeed the most common route. However, the inter- and intramolecular hydrogen transfers were also found to be valid, which was contradictory to previous energy minimization calculation results. The simulations agreed well with known experimental data in terms of activation energy and reaction side products. The main products are H_2O , CO_2 , and N_2 .

5.2.1.6 Chemical Analysis of FOX-7

Accurate methods for analysis of FOX-7 are required for quality control and to identify contaminants which may be carried over from the production process starting with 2-methylpyrimidine-4,6(1H,5H)-dione.

Three different synthetic routes to FOX-7 were developed and potential by-products were identified by HPLC. The route starting from 2-methyl-pyrimidine-4,6-dione is the method currently used for production of FOX-7 on a pilot plant scale in Sweden. Based on this route, an HPLC-UV-MS method was developed for the analysis of FOX-7, its precursors, and all major by-products [205].

FOX-7 can be analyzed by thin-layer chromatography [206] or by HPLC [207]. For HPLC, two different mobile phases with different pH values, i.e., acetonitrile–water and methanol–water with ammonia and trifluoroacetic acid, were used.

5.2.1.7 Burning Rates of FOX-7

Strand burning rates of FOX-7 were investigated over the 0.2–35 MPa pressure range, where FOX-7 burned slightly slower than RDX [185]. The temperature distribution in the combustion waves of FOX-7 has been measured at pressures from 0.2 to 1.1 MPa.

5.2.1.8 Detonation Velocities of FOX-7

The measured detonation velocity for FOX-7 pressed pellets with 25-mm diameter and a density of 1.780 g/cm^3 was $8325 \pm 80 \text{ m/s}$ [208]. For comparison, a theoretical detonation velocity was estimated by using the thermochemical code CHEETAH [209] with two sets of the Becker-Kistiakowsky-Wilson equation of state (BKW) parameters. Calculated detonation velocity was 8453 and 8499 m/s for BKW-CHEETAH and

BKW-Sandia data sets, respectively. The average heat of detonation from three tests in a calorimetric bomb of volume 5.6 dm^3 filled with argon at a pressure of 2 MPa was $4860 \pm 60 \text{ J/g}$. The isentrope and the constant-gamma isentrope for the detonation products of FOX-7 were also found. See also [210]. Another source gave the detonation velocity of FOX-7 as 8869 m/s.

5.2.1.9 Safety Properties of FOX-7

Drop-Weight (Impact) Sensitivity of FOX-7

The drop-weight (impact) sensitivity of FOX-7 is 20–40 Nm [2]. The drop-weight (impact) sensitivity of as-received and dried FOX-7 was 7.5–15 Nm, and that of re-precipitated FOX-7 was 20 Nm. The particle size has an important influence on FOX-7 sensitivity. Changing to a smaller particle size caused impact and friction sensitivity to increase [211]. After replacing RDX in composition B partially with FOX-7, the mechanical sensitivity of the formulation hardly changed, and the effect of decreasing the sensitivity was very obvious. The results showed that selecting the right particle size and applying a surface coating is an important step to decrease the mechanical sensitivity of FOX-7. FOX-7 that is considered as a replacement for RDX in PBX needs to have good bonding to the fluoropolymer binder [212]. The inter-facial energy and wetting of FOX-7 particles with fluoropolymers are similar to those of TATB. In both cases this will affect the impact sensitivity of the PBX.

The impact sensitivity of coarse DADNE was determined using a drop-weight testing apparatus with a 5-kg hammer [213]. The highest drop height was determined at which no reaction was observed (h_0). Ten trials were conducted at consecutive heights which were changed in steps of 1 cm. The value of 23 cm was found as h_0 , which corresponds with the impact energy of 11.3 J. For comparison, a value of 6 cm (2.9 J) was determined for crystalline RDX under the same conditions.

Slightly different impact energies of 15.5 and 12.4 J were determined for FOX-7 crystals with sizes of 250–355 μm and those with sizes less than 70 μm . A 2-kg drop-weight apparatus was used in these tests and the drop heights were 79 and 63 cm, respectively [152].

The impact sensitivity can also be expressed as the drop height at which 50% initiations occurred (h_{50}). To determine h_{50} for FOX-7, the Bruceton procedure (an up-and-down method) was applied. The total number of tests performed was 30. The medium height was at $h_{50} = 35.2 \text{ cm}$. This height corresponds to an impact energy of 17.3 J. For comparison, the value of 9.6 J was determined for crystalline HMX in the same apparatus.

Friction Sensitivity of FOX-7

The friction sensitivity of FOX-7 is $>550 \text{ N}$ [2]. The friction sensitivity of as-received and dried FOX-7 was 320–324 N, and that of re-precipitated FOX-7 was $>360 \text{ N}$ [158, 159]. The friction sensitivity of FOX-7 was measured on a Julius–Peters machine. No friction

sensitivity was observed up to loading of 353 N for different types of FOX-7 crystals (coarse and fine particles of FOX-7) [214].

Card Gap Sensitivity of FOX-7

The shock sensitivity of FOX-7 was determined by using a gap test. The sensitivity of fine-grain FOX-7 is lower than that of TNT, but the coarse-grain FOX-7 is much more sensitive than TNT [215].

ESD Sensitivity of FOX-7

The ESD sensitivity of as-received and dried FOX-7 was 4.5 J, identical to that of RDX [158, 159].

Cook-Off Behavior of FOX-7

Small-scale safety tests showed that PBX compositions with FOX-7 were not sensitive to friction and the thermal stability was excellent, at 65 °C. Larger-scale detonation tests and small-scale slow cook-off tests showed that the FOX-7-based PBX did not detonate at a diameter of 25 mm and upon slow (3.3 °C/h) heating in a cook-off test, it ignited at 220 °C and burned without damage to the container or the surroundings. See also [210].

5.2.1.10 Environmental Impact of FOX-7

FOX-7 is not biodegradable. The toxicity to aquatic organisms as measured by effective control to 50% growth inhibition (EC₅₀) is 530 mg/mL.

FOX-7 was among four other explosives and oxidizers, including ADN, evaluated as replacements for AP and examined for environmental fate chemistry and potentially persistent pollution [216]. This was investigated in detail to make sure that spilled energetic materials would not cause the same long-term problems in the ground water and aquifers as AP. The oral toxicity of FOX-7 in rats is LD₅₀ = 200–2000 mg/L.

5.3 Substituted Derivatives of 1,1-Diamino-2,2-dinitroethene

The reactivity of FOX-7 was studied in the hope of finding energetic compounds that have higher energy but at least the same thermal stability as FOX-7. Various reactions like cycloadditions, nitration, halogenation, and acylation were performed in order to evaluate the reactivity of the C=C double bond and the amino moieties [179, 217]. Several products were isolated and two of them were characterized by XRD. Two reactive sites on the 1,1-diamino-2,2-dinitroethene molecule were identified. Reaction of FOX-7 with acetic acid gives an acetyl-substituted NH group. Primary amines reacted with FOX-7 to afford *N*-substituted and *N,N'*-disubstituted-1,1-diamino-2,2-dini-

troethenes via transamination reactions. Treatment of FOX-7 with hydrazine led only to the monosubstituted product 1-amino-1-hydrazino-2,2-dinitroethene.

Other derivatives of 1,1-diamino-2,2-dinitroethene exhibit good thermal stability, high density, positive heat of formation, acceptable oxygen balances, and excellent detonation properties, which often are superior to those of RDX [218].

5.3.1 1-Amino-1-hydrazino-2,2-dinitroethene

1-Amino-1-hydrazino-2,2-dinitroethene (AHDNE) was synthesized from hydrazine hydrate and FOX-7 in water [219]. Single crystals suitable for XRD measurement were obtained by slow evaporation of the solvent methanol at room temperature. The crystals belong to an orthorhombic system with space group *Pnma* and cell parameters of $a = 0.6283(4)$ nm, $b = 0.7713(5)$ nm, $c = 1.2280(8)$ nm, $\alpha = \beta = \gamma = 90^\circ$, $V = 0.5950(7)$ nm³, and $\rho_c = 1.821$ g/cm³.

1-Amino-1-hydrazino-2,2-dinitroethene and its salts were characterized by IR, NMR, elemental analysis, DSC, density, and impact sensitivity measurements [220]. 1-Amino-1-hydrazino-2,2-dinitroethene decomposed at 397.6 K (124.5 °C) and the salts decomposed over the range 411.7–454.7 K (138.6–181.6 °C), thus showing higher thermostability than the parent compound. The calculated detonation pressures for these salts ranged from 27.2 to 37.8 GPa, and detonation velocities were predicted to be between 8424 and 9482 m/s; these properties make them competitive energetic materials.

The thermal behavior and non-isothermal kinetics of the exothermic decomposition of 1-amino-1-hydrazino-2,2-dinitroethylene (AHDNE) were studied by DSC and TG/DTG [221]. The reaction rate equation was

$$\frac{d\alpha}{dT} = 10^{19.29} (1 - \alpha) \exp(-1.88 \times 10^4 / T) / \beta$$

The critical temperature of thermal explosion was calculated as 371 K (98 °C). The specific heat capacity of AHDNE was determined, and the standard molar specific heat capacity was 212 J mol⁻¹ K⁻¹ at 298 K. AHDNE was relatively unstable and had a much lower thermal stability than 1,1-diamino-2,2-dinitroethylene.

The potassium salt of AHDNE was synthesized by reacting AHDNE and potassium hydroxide in methanol aqueous solution [222]. The thermal behavior of K(AHDNE) as studied using DSC and TG/DTG is a three-step process. The decomposition enthalpy, apparent activation energy, and pre-exponential factor of the first decomposition process were -2662 J/g, 185 kJ/mol, and 10^{19.63} s⁻¹, respectively. K(AHDNE) had better thermal stability than AHDNE. Similar observations were made with the cesium salt [223].

A high-nitrogen energetic salt, the guanidinium salt of 1-amino-1-hydrazino-2,2-dinitroethylene guanidine, G(AHDNE), was synthesized by reacting 1-amino-1-hydrazino-2,2-dinitroethylene (AHDNE) and guanidinium chloride in sodium hydroxide aqueous solution [224].

The thermal stability of G(AHDNE) was determined by DSC and TG-DTG, showing an intense exothermic decomposition. The enthalpy, apparent activation energy, and pre-exponential constant of the decomposition process were -1060 J/g , 148.7 kJ/mol , and $10^{15.9} \text{ s}^{-1}$, respectively. The critical temperature of thermal explosion of G(AHDNE) was $425 \text{ K} = 152^\circ\text{C}$. The adiabatic time-to-explosion of G(AHDNE) was calculated to be between 60 and 72 s. The detonation velocity and detonation pressure were also estimated. G(AHDNE) is suitable as a nitrogen-rich propellant ingredient.

5.3.2 1-Amino-1-methylamino-2,2-dinitroethene

Replacing one of the amino groups in DADNE with a methylamino group may improve the thermal stability of the molecule. These compounds can be prepared by transamination reactions, replacing one of the amino groups with an alkylamino group.

1-Amino-1-methylamino-2,2-dinitroethylene (AMFOX-7), was synthesized from 1,1-diamino-2,2-dinitroethylene reacting with methylamine in *N*-methyl pyrrolidone (NMP) at 353 K (80°C), and its structure was determined by single-crystal XRD [225, 226]. The crystal is monoclinic, space group $P2_1/m$ with crystal parameters of $a = 6.361(3) \text{ \AA}$, $b = 7.462(4) \text{ \AA}$, $c = 6.788(3) \text{ \AA}$, $\beta = 107.367(9)^\circ$, $V = 307.5(3) \text{ \AA}^3$, $Z = 2$, and $\rho_c = 1.751 \text{ g} \cdot \text{cm}^{-3}$. The enthalpy, apparent activation energy, and pre-exponential constant of the exothermic decomposition reaction of AMFOX-7 were -303 kJ/mol , 230.7 kJ/mol , and $10^{21.03} \text{ s}^{-1}$, respectively. The critical temperature of thermal explosion is 518.4 K (245.3°C). AMFOX-7 has higher thermal stability than FOX-7.

A similar compound can be obtained by replacing one amino group in DADNE with an ethylamino group instead of a methylamino group. 1-Amino-1-ethylamino-2,2-dinitroethylene (AEFOX-7) was synthesized by the reaction of FOX-7 and ethylamine aqueous solution at 365 K (92°C) [227]. The thermal behavior of AEFOX-7 was studied by DSC and TGA/DTA, and can be divided into a melting process and an exothermic decomposition process. The enthalpy, apparent activation energy, and pre-exponential constant of the exothermic decomposition reaction were -375 kJ/mol , 169.7 kJ/mol , and 10^{19} s^{-1} , respectively. The critical temperature of thermal explosion of AEFOX-7 was 418.3 K (145.2°C). The thermal stability of AEFOX-7 was much lower than that of FOX-7.

5.4 Tetranitroethylene

Tetranitroethylene (tetranitroethene) had not previously been isolated but was suspected as an intermediate in the reaction of hexanitroethane with anthracene [228]. It is one of the known nitrocarbons which do not contain any hydrogen.

Tetranitroethylene was later isolated in 50% yield by flash vacuum pyrolysis of hexanitroethane [121]. Critical for the isolation was a trap temperature such that dinitrogen tetroxide was not condensed. Tetranitroethylene reacted quantitatively with anthracene to give 11,11,12,12-tetranitro-9,10-dihydro-9,10-ethanoanthracene. Tetranitroethylene was at least an order of magnitude more reactive in Diels–Alder additions than tetracyanoethylene. Tetranitroethylene reacted with cyclopentadiene to give 5,5,6,6-tetranitronorbornene. Tetranitroethylene is a suitable intermediate for the synthesis of other nitro compounds that might be useful as propellant ingredients.

6 Nitroalkynes

Nitroacetylene (nitroethyne), or maybe even dinitroethyne, would be very energetic compounds, but they have not yet been prepared in a pure state. Dinitroacetylene and other nitroacetylenes would be attractive precursors to high-energy-density materials, but suffer from high reactivity and thermal instability. Dissolved nitroacetylene can be prepared by the reaction of NO_2PF_6 with trimethylsilylacetylene [229, 230]. It was stable at room temperature in dilute solution for about a week. The ^1H and ^{13}C NMR spectra of nitroacetylene revealed strong ^1H – ^{14}N and ^{13}C – ^{14}N spin couplings. Nitroacetylene reacted rapidly with nucleophiles. It gave a 1,4-Diels–Alder adduct with cyclopentadiene. It has been attempted to stabilize nitroethynes as ligands in metalorganic complexes with cobalt carbonyl or by attaching a trimethylsilyl group.

The reaction of nitroacetylene with furan or vinyl ethers gave nitrovinylisoxazoles. Mechanisms were proposed that would account for these unexpected products. The mechanisms were modeled computationally in vinyl methyl ether, calculating ΔH and the activation barriers [231]. Using other computational procedures, the molecular geometry of nitroacetylene, the gas- and liquid-phase heats of formation, and the molecular surface electrostatic potential of nitroacetylene were calculated.

The C– NO_2 bond dissociation energy in nitroethyne has been calculated and indicated that this molecule is expected to be very unstable [232]. Another potential but as yet unknown energetic compound is 1-azido-2-nitroethyne. Only calculations of the molecular structure and heat of formation of 1-azido-2-nitroethyne have been reported.

Forty-five years after their first preparation, nitroalkynes retain interest for their unique chemical behavior and their potential as energetic materials or building blocks for cycloadditions to heterocyclic compounds [233, 234].

1,1,1,6,6,6-Hexanitrohexyne-3 can be made by a metathetical reaction between silver nitroform and 1,4-dibromo-butyne-2 or 1,4-dichlorobutyne-2 in an inert volatile solvent [235]. It is a white crystalline solid which melts at 402.5–402.8 K (129.4–129.7 °C). It is detonated by a hammer blow. Ignition temperature is 478 K (205 °C).

7 Straight-Chain C₃ Polynitropropanes

7.1 Dinitropropanes

Geminal dinitro compounds can be prepared by catalyzed oxidative nitration of nitronate salts [236]. This method avoids the use of silver salts and instead uses a mixture of peroxydisulfate and potassium hexacyanoferrate(III). 2,2-Dinitropropanol is an intermediate in the synthesis of energetic plasticizers.

2,2-Dinitropropane forms face-centered, cubic crystals at room temperature, with $a_0 = 8.78 \pm 0.05 \text{ \AA}$ and four molecules per unit cell [237].

The pyrolysis of 2,2-dinitropropane vapor was investigated at 448 to 483 K (175 to 210 °C) [238]. Mass spectrometric analyses of the early products of the reaction indicated that the initial products were acetone, NO, and NO₂ in equimolar amounts. As acetone and NO₂ accumulated, the NO₂ was reduced to NO by reaction with acetone to yield H₂O, CO, and CO₂.

The heats of combustion of 1,1-dinitropropane, H₃CCH₂CH(NO₂)₂; 2,2-dinitropropane, (H₃C)₂CH(NO₂)₂; and 1,3-dinitropropane, O₂N(CH₂)₃NO₂, are 1867, 1850, and 1814 kJ/mol (446.3, 442.2, and 433.6 kcal/mol), respectively [26].

The thermal explosion times of some isomeric dinitropropanes at a constant pressure of 10 kbar were measured in the temperature range 403–583 K (130–310 °C) [239]. For a constant thermal explosion time of 20 s, the dinitropropanes that did not have a hydrogen atom on the same carbon as the dinitro group required a higher temperature than those that did have such a hydrogen. Specifically, the temperatures corresponding to a 20-s explosion time at 10 kbar pressure were 2,2-dinitropropane 542 K (269 °C), 1-fluoro-1,1-dinitropropane 515 K (242 °C), 1,1-dinitropropane 445 K (172 °C), and 1,2-dinitropropane 435 K (162 °C). The physical properties of 1,1- and 2,2-dinitropropane are summarized in Table 17. See also [240, 241].

The thermal decomposition of 1,1-dinitropropane and 2,2 dinitropropane was compared to better understand the effect of the location of nitro groups on the stability of nitro compound molecules. The thermal decomposition of neat, liquid 1,1-dinitropropane (1,1-DNP) at 1 and 1000 atm and 408–428 K (135–155 °C) gave over 90% propionic acid with small amounts of acetic acid, with conversions ranging from 29% in 1.5 h at 408 K (135 °C) and 1000 atm to 10% in 21 h at 428 K (155 °C) and 1 atm [243]. At 1000 atm and 155 °C, decompositions were unpredictable, sometimes proceeding smoothly for up to 125 min and at other times exploding after only 25 min. 2,2-Dinitropropane (2,2-DNP), in contrast, decomposed slowly at 438 K (165 °C) to

Table 17: Physical and thermodynamic properties of 1,1- and 2,2-dinitropropane at 60 °C.

Property	Compound	
Abbreviation	1,1-DNP	2,2-DNP
CAS RN	[601-76-3]	[595-49-3]
Molecular mass, g/mol	134.1	134.1
Density, g/cm ³	1.201 ± 0.01	1.221 ± 0.01
Coefficient of thermal expansion, K ⁻¹	(~1.0 ± 0.1) × 10 ⁻³	(~0.98 ± 0.1) × 10 ⁻³
Velocity of sound, mm/μs	1.33 ± 0.05	1.24 ± 0.05
Enthalpy of formation, cal/g	-283 ± 20	-300 ± 20
Detonation velocity, mm/μs	6.414 ± 0.018 at 25 °C	6.318 at 60 °C
Unconfined failure diameter, mm	>15 at 25 °C	>38 at 60 °C

Data source: [242]

give only acetone, NO₂, and NO. Pressure retarded the reaction slightly. At 463 K (190 °C), 2,2-DNP had a half-life of 15 h. The unimolecular decomposition of four dinitropropanes has been studied in the gas phase using a low-pressure pyrolysis technique. 1,2-Dinitropropane was found to undergo cyclic elimination of HONO, giving 1- and 2-nitropropene. Three *gem*-dinitroalkanes, 1,1-DNP and 2,2-DNP and 1-fluoro-1,1-dinitropropane, underwent C–N scission rather than HONO elimination, with essentially the same rate constant. Major decomposition products in these cases were propionaldehyde and acetone in the case of the 1,1- and 2,2-dinitropropanes, and propionyl fluoride in the case of 1-fluoro-1,1-dinitropropane. The detonation failure diameters of four liquid nitroalkanes (nitromethane, 1,1-dinitroethane, 1,1-DNP, and 2,2-DNP) were measured for the cases of heavy confinement in thick-walled lead cylinders and weak-shell confinement (Table 17).

The thermal decomposition of 2,2-DNP was investigated in a shock tube over the temperature range 970–1200 K, under high dilution in argon at total pressures of 456–557 kPa (4.5–5.5 atm) [36]. The decay of 2,2-DNP and the production of NO₂ were followed spectrophotometrically at 280 and 405 nm, respectively. The derived unimolecular rate constant for dissociation was

$$k_{\infty} = 10^{13.1} \exp(-23000/T) \text{ s}^{-1}.$$

The products of pyrolysis of 2,2-DNP were identified and quantified using FTIR, GC, and GC/MS. The principal products were CO, NO, (CH₃)₂CO, CH₃C≡H, CH₂C=CH₂, CH₃CN, CO₂, CH₃OH, CH₄, H₂O, and CH₂O. The first step in the decomposition appears to be C–NO₂ bond fission. However, the temporal profiles of NO₂ during the decomposition were distinctively different from those recorded during the decomposition of CH₃NO₂ or 2-nitropropane. The following intermediates play critical roles in the decomposition: H, OH, NO₂, HCO, and HNO.

8 C_{n>3} Polynitroalkanes

8.1 Straight-Chain C_{n>3} Polynitroalkanes

The physical properties of trinitroalkanes with terminal trinitromethyl groups are listed in Table 18. Although these compounds have a better oxygen balance than the mononitroalkanes, they have not found any applications as propellants.

Compared with the well-established 2,2,2-trinitroethyl group in the chemistry of energetic materials, the 3,3,3-trinitropropyl group is less investigated regarding its chemical and energetic properties. Syntheses of several compounds containing the 3,3,3-trinitropropyl group were performed and their properties compared with compounds containing the 2,2,2-trinitroethyl group [244]. All materials were thoroughly characterized by XRD, DSC, and their sensitivities towards impact, friction, and electrostatic discharge. The energies of formation were calculated and several detonation parameters such as the velocity of detonation and the propulsion performance were estimated with the program package EXPLO5.

Reactions of nitric acid, dinitrogen tetroxide, or dinitrogen pentoxide with alkenes result in mixtures of dinitro and nitro/nitrate compounds. Oxidation of oximes or isocyanates leads to conversion of the oxime or isocyanate ligand to a nitro group. The chemistry of polynitroalkanes becomes more and more complex the more carbon atoms are in the skeleton backbone and the more nitro groups are attached. Some of these polynitroalkanes serve as intermediates in the synthesis of other, more useful nitro compounds.

There are many energetic compounds that contain nitro —NO₂ as well as nitrate —ONO₂ groups. We could discuss these compounds either here in the chapter “Nitroaliphatic Compounds” or later in the chapter “Nitrate Esters.” A compromise was achieved by deciding that those which contain more nitro groups than nitrate (nitroxy) groups or equal numbers of both will be discussed here and those that contain more nitrate (nitroxy) groups than nitro groups will be discussed later.

Geminal dinitro compounds can be obtained by the reaction

Table 18: Physical properties of trinitroalkanes.

Compound name	Formula	Boiling point		Melting point		Density g/cm ³	Refractive index <i>n_D</i>

Data source: [108]

The reaction of nitroethane, potassium hydroxide, formaldehyde, potassium nitrite, and potassium persulfate in the presence of potassium ferricyanide as a catalyst gave a reaction mixture from which 2,2-dinitropropanol could be extracted with ether [245]. A continuous process has been developed for the production of 2,2-dinitropropane by nitration of 2-nitropropane [246]. 2,2-Dinitropropane is used as an additive in diesel fuels.

The time lag prior to explosion of six trinitromethyl explosives: 2,2,2-trinitroethyl-*N*-nitromethyl amine (TNMA), bis(2,2,2-trinitroethyl-*N*-nitro) ethylene diamine (BTNEDA), 2,2,2-trinitroethyl-4,4,4-trinitrobutyrate (TNETB), bis(2,2,2-trinitroethyl) formal (BNTF), 1,1,1,3-tetranitropropane (TETNP), and bis(2,2,2-trinitroethyl)-nitramine (BTNNA) at different temperatures was measured by an explosion temperature test apparatus and the apparent activation energy and pre-exponential constant of the explosive decomposition rate equation and the value of T corresponding to time lag $t = 5$ s were calculated [247]. The thermal stability of the six trinitromethyl explosives decreased in the order TNETB > BNTF > BTNEDA > TETNP > TNMA > BTNNA.

The theoretical chemical mechanisms involved in the decomposition of trinitroethyl compounds were studied for both aliphatic and aromatic derivatives using density functional theory calculations [248]. At first, in the case of 1,1,1-trinitrobutane, two primary channels were highlighted among the five investigated ones: the breaking of the C—N bond and HONO elimination. Then, the influence of various structural parameters was studied for these two reactions by varying the length of the carbon chain or adding substituents or double bonds along the carbon chain.

Trinitroalkyl compounds with positive oxygen balance were evaluated as non-toxic, environmentally friendly replacements for AP in composite solid propellants [249].

A unique trinitroalkyl compound is (2,2,2-trinitroethyl) carbonate, $C_5H_4N_6O_{15}$, which contains 61.83% oxygen [250]. Intra- as well as inter-molecular C—H $\cdots$ O and dipolar nitro-group interactions account for its exceptionally high density of 1.975 g/cm³. For a given volume, this compound contains available oxygen in amounts even superior to that of liquid oxygen.

8.2 Branched-Chain Polynitroalkanes

While most nitro compounds that have been considered as energetic plasticizers were derived from straight-chain alkanes, there are a few polynitroalkanes based on branched-chain alkanes, such as 2,3-dimethyl-2,3-dinitrobutane (DMDNB) where rotation along the C—C axis is hindered and rotational isomers may be observed by IR spectroscopy [251]. This appears to be a thermally more stable nitroalkane [252]. In the DTA, it had a phase change at 383.4 K (110.3 °C), and the start of an exotherm

at 478.5 K (205.4 °C) and a sharp exotherm at 521 K (248 °C) when tested in closed test cells. DMDNB is used as a more volatile tracer for PBX to make them more detectable at security check points.

8.3 Cycloaliphatic Polynitroalkanes

Laser-induced chemistry possesses the potential to drive some nitration reactions in an efficient and selective manner, such as in the laser-induced reaction of nitrogen dioxide with each of three cycloalkanes [253]. A carbon dioxide infrared laser was used to drive the reaction between nitrogen dioxide and cyclopropane, cyclobutene, or cyclopentane under a variety of reaction conditions. The major products resulted from either ring cleavage or product dissociation, nitration, or oxidation. The product mixtures were found to be highly sensitive to the specific reaction conditions.

Nitrocyclobutane would be more energetic than nitro-*n*-butane or nitroisobutane because the strained ring adds to the energy content. Aminocyclobutanes can be oxidized to the corresponding nitrocyclobutanes. 1,3-dinitrocyclobutane, 1,1,3-trinitrocyclobutane, and 1,1,3,3-tetranitrocyclobutane have been synthesized, but only in trace quantities.

8.3.1 Nitrocyclopropanes

The heat of formation of the parent hydrocarbon, cyclopropane, is approximately +276 kJ/mol with a corresponding bond strain energy of 230 kJ/mol. The enthalpy of combustion of cyclopropane is 2091.3 kJ/mol, or about 49.8 kJ/g⁻¹. Consequently, polynitro derivatives of cyclopropane and spirocyclopropane should be very energetic materials [254]. The idea of adding oxidizing groups like nitro groups to the cyclopropane backbone is not new. Nitrocyclopropane, C₃H₅NO₂, was prepared by mixing cyclopropane vapors with N₂O₄ at 693–728 K (420–455 °C) or with HNO₃ vapors at 663–683 K (390–410 °C) for several seconds in a spiral Pyrex tube, then immersing the tube in an ice water bath and collecting and purifying the resulting liquid [255]. Nitrocyclopropane was isolated in 4–15% yield; the boiling point was 338–340 K (65–67 °C) and the density was 1.136 g/cm³. It was noted that nitrocyclopropane was relatively unreactive towards oxidation, bromination, or the presence of alkalis. Nitrocyclopropane does not form salts in strong alkaline media as *n*-nitropropane would. It can be reduced to cyclopropyl amine.

trans-1,2-Dinitrocyclopropane was synthesized by oxidative cyclization of the corresponding open-chain 1,3-dinitronate dianions with iodine in dimethyl sulfoxide [256]. *trans*-1,2-Dinitrospiropentane was prepared using a similar strategy with 43% yield by treating the dianion of 1,1-bis(nitromethyl)-cyclopropane [257]:

Nitrocyclopropanes can be prepared from nitrodiazomethanes [258, 259].

Density functional theory calculations of cyclopropane molecules with three or more nitro groups suggested that all molecules can exist as minimum-energy stationary states [260]. Some nitrocyclopropanes have a specific enthalpy of decomposition in excess of 8 kJ/g. Table 19 lists the calculated enthalpies of formation and the resulting enthalpies of combustion and decomposition of several nitrocyclopropanes. The enthalpies of formation are all positive and become more so as the nitro content of the molecule increases. This is consistent with an increased steric interference, as bulky nitro groups start amassing on the second side of the cyclopropane backbone.

Table 19: Enthalpies of reaction and formation of nitrocyclopropanes.

	ΔH_f	ΔH_{comb}	ΔH_{decomp}	
	kJ/mol	kJ/mol	kJ/g	kJ/mol
Trinitrocyclopropane	73.8	1683.1	9.51	-1258.6
Tetranitrocyclopropane	114.9	—	—	-1611.3
Pentanitrocyclopropane	244.1	—	—	-1567.6
Hexanitrocyclopropane	338.2	—	—	-1518.7

Data source: [260]

8.3.2 Nitrocyclobutanes

Aminocyclobutanes can be oxidized to the corresponding nitrocyclobutanes when using *m*-chloroperoxybenzoic acid (*m*-CPBA) as the oxidant. Using this strategy, 1,3-dinitrocyclobutane was prepared from 1,3-diaminocyclobutane in 38% yield. Oxidative nitration of the disodium salt of 1,3-dinitrocyclobutane with a mixture of silver nitrate and sodium nitrite generated a mixture of 1,1,3,3-tetranitrocyclobutane $\text{C}_4\text{H}_4\text{N}_4\text{O}_8$ and 1,1,3-trinitrocyclobutane, from which the former was isolated in 38% yield after fractional recrystallization [261, 262]:

1,1,3,3-Tetranitrocyclobutane had a crystal density of 1.83 g/cm³, and although the compound rapidly degraded in alkaline solution, it was thermally stable up to its melting point of 438 K (165 °C).

XRD of 1,1,3,3-tetranitrocyclobutane single crystals gave the following crystal structure parameters: triclinic crystals, space group $P\bar{1}$, $a = 6.301(1) \text{ \AA}$, $b = 7.858(1) \text{ \AA}$, $c = 8.736(1) \text{ \AA}$, $\alpha = 85.88^\circ$, $Z = 2$ (two half molecules per asymmetric unit), and $\rho_{\text{XRD}} = 1.831 \text{ g/cm}^3$ [263]. The cyclobutane rings are exactly planar (each one sits on a separate crystallographic inversion center) with the *gem*-dinitro substituents disposed symmetrically above and below the ring plane.

The 1,3,3-trinitro derivative of azacyclobutane, TNAZ, is a new explosive and energetic additive to propellants that has been thoroughly investigated. The properties of TNAZ are discussed in *Encyclopedia of Liquid Fuels*, chapter "Heterocyclic Amines", based on the structure of the ring molecule to which the nitro groups have been attached.

8.3.3 Nitrocyclohexanes

The thermal decomposition of 1,1-dinitro-cyclohexane and 1,1,4,4-tetranitrocyclohexane was compared to that of 1,4-dinitropiperazine and other nitramines and difluoroamino compounds [264]. Geminal bis(difluoroamino) compounds appeared to be somewhat more stable than the corresponding *gem*-dinitro compounds, though they released more heat during decomposition. The decomposition of *gem*-bis(difluoroamino) and *gem*-dinitro compounds exhibited similarities. Both experienced loss of one geminal NX₂ group followed by the rearrangement of the remaining —NX₂. Where X was oxygen, loss of the initial nitro by homolysis was favored; rearrangement of the remaining nitro followed by homolysis of NO resulted in a CO bond. The density of nitrocyclohexane is 1.061 g/cm³.

9 Bridged and Fused-Ring Structure Cycloaliphatic Polynitroalkanes

There is a group of bridged hydrocarbons which have found application as high-density fuels for air-breathing cruise missiles and similar applications. It would be of interest to combine these energetic hydrocarbon skeletons with one or more nitro groups to soup up the energy content of the material to beyond that of a fuel and maybe reaching that of a monopropellant or explosive. The all-hydrocarbon skeleton analog to RDX or HMX would still be a very energetic molecule, even without the nitramine linkages.

Bicyclo[1.1.1]pentane is a highly strained hydrocarbon system due to close proximity of non-bonded bridge head carbons, and attaching nitro groups would make it even more energetic. Densities, detonation velocities, and detonation pressures for a series of polynitrobicyclo[1.1.1]pentanes, as well as their thermal stabilities were investigated by computational chemistry [265]. Calculations of the bond length and bond dissociation energies of the C—NO₂ bond indicated that this may be the possible trigger bond in the pyrolysis mechanism. 1,2,3-Trinitrobicyclo[1.1.1]pentane, 1,2,3,4-tetranitrobicyclo[1.1.1]pentane, and 1,2,3,4,5-pentanitrobicyclo[1.1.1]pentane have promising predicted energetic characteristics with better stability and insensitivity.

A highly strained ring molecule is [1.1.1]propellane, where not only two but three cyclopropyl rings share a common side of three triangles. In [2.2.2]propellane, three cyclobutane rings share one side of the squares. Nitro groups can be attached to the free >C—H bridges in these molecules [266].

10 Caged Cycloaliphatic Polynitroalkanes

Energetic compounds based on strained or caged alicyclic skeletons with one or more nitro groups attached have received substantial interest because of their high density and high detonation velocities. The synthesis of these compounds poses a challenge for the synthetic chemist. An excellent summary of synthetic efforts to prepare nitrocubanes and similar compounds is presented in [267]. Initial evaluation of the shock sensitivity of such compounds showed that they are relatively insensitive to shock but have a higher density than some of their open-chain aliphatic analogs.

Similar cubanoid structures called azacubanes in which one or more CH groups in the corner of the cube have been replaced by nitrogen have been considered. The gas-phase enthalpies of formation of azacubanes with many nitro groups have been obtained via isodesmic reactions in which the azacubane cage skeleton is not destroyed [268]. After full nitration of 1,4-diazacubane or 1,3,5,7-tetraazacubane, the weakest C—N bond in the 1,3,5,7-tetraazacubane cage skeleton strengthens slightly, but in the 1,4-diazacubane cage skeleton, it weakens. For highly nitrated azacubanes, the introduction of an —NH₂ group results in destabilization of the neighboring

C—N bond in the cage skeleton. The shock stability of 2,4,6,8-tetranitro-1,3,5,7-tetraazacubane (TNTAzC) is superior to that of 2,3,5,6,7,8-hexanitro-1,4-diazacubane (HNDaZC). The detonation velocity and pressure of TNTAzC are predicted to reach 11.10 km/s and 101.7 GPa, respectively.

Another caged cycloaliphatic alkane is tetrahedrane, where the four sides of a tetrahedron are formed by cyclopropane rings. The parent hydrocarbon is not known, but derivatives tetra(*tert*-butyl)tetrahedrane and tetra(trimethylsilyl)tetrahedrane are known. It was hoped that attachment of nitro groups to form tetranitrotetrahedrane (another nitrocarbon) would stabilize the molecule, but the opposite rather appears to be the case. This compound exists so far only in the imagination of computational chemists. The predicted properties of nitrotetrahedranes were compared to the properties of nitrocubanes.

Computational studies on a series of nitro derivatives of tetrahedrane were carried out by optimizing the molecular geometries and calculating the vibrational frequencies [269]. The electronic structures were analyzed using natural bond orbital theory and atoms in molecules theory. The results showed that the skeleton, a tetra-carbon cage, is heavily stressed. C—C bonds of tetrahedrane are weaker than normal C—C bonds. The introduction of a nitro group reduces the stability of the tetra-carbon cage and the C—N bond is still weak. The more nitro groups are introduced, the weaker the C—N bonds are. For $C_4(NO_2)_4$, the C—N bond is more readily broken than the C—C bond. Heats of formation of nitro derivatives were calculated by assuming isodesmic reactions. Values of heats of formation were all positive and increased with an increase in the number of nitro groups.

Compounds containing carbon-based cages have a highly strained molecular structure and have become a subject of interest because they possess high heats of formation and are highly energetic. *Ab initio* density functional theory molecular modelling calculations have been performed to analyze 28 carbon-cage structures with the aim of identifying the best candidates for synthesis and for use in propellant compositions [270]. Calculated heats of formation and densities of the compounds were then used to compute their specific impulses and density-specific impulses in various configurations (solid and liquid). Detonation properties of the compounds have also been calculated and a correlation of the properties of the cage compounds with their molecular structures was attempted.

10.1 Nitrocubanes

The cubane skeleton has a high enthalpy of formation (+620 kJ/mol = +148 kcal/mol) because it has a lot of internal molecular strain. Nitro derivatives of cubane would give a better performance as propellants or explosives than nitroadamantanes because in adamantane, 6-membered rings are similar to unstressed cyclohexane.

In theory, it should be possible to replace all eight hydrogens on cubane with nitro groups and arrive at a very energetic molecule $C_8(NO_2)_8$ that does not contain any hydrogen. The molecular mass of octanitrocubane is 464.1 g/mol and the oxygen balance is $\pm 0.0\%$. A propellant that does not contain hydrogen would not form any water as the product of combustion and thus have no condensables in the exhaust, making it a low-signature or no-signature propellant which may have tactical advantages for certain military applications. It was predicted that octanitrocubane would enhance the energy output of propellants and explosives by 14% compared to HMX.

There has been a substantial experimental effort to synthesize nitrocubanes. These compounds have so far only been obtained in gram quantities and it is unlikely that they will ever be used as rocket propellants. They are primarily intended as explosives. They are more of academic interest but may show pathways for synthesis of more energetic rocket propellants, possibly by direct synthesis from readily available raw materials such as acetylene or ethene and dinitrogen tetroxide. Systematic studies on the effect of increasing the number of nitro groups attached to a caged molecule have given us a better understanding of the internal workings of energetic materials, and this knowledge can be applied to other propellants, not only explosives. This is the reason for the nitrocubanes being listed in this book, particularly work conducted within the last decade. The interest in nitrocubanes has stimulated work on other cubane derivatives, mostly cubylcarbonic acids and aminocubanes that are used as intermediates in the preparation of nitrocubanes. It is very misleading to learn that the dimethyl ester of cubane-1,4-dicarboxylic acid is now (as of 2013) produced on the **pilot scale** [271], but when reading the details of the paper it becomes apparent that they are only making several grams at a time.

The plain cubane hydrocarbon (without any nitro groups) has been considered as a fuel for solid fuel air-breathing ramjets and as a building block for binders for solid propellants (See *Encyclopedia of Liquid Fuels*, chapter “Cycloaliphatic Hydrocarbons”) but of course the limited quantities available have prevented any such use. Cubane is a kinetically stable compound (decomposition temperature above 473 K = 200 °C), and a thermodynamic store of energy ($\Delta H_f = +620$ kJ/mol) which corresponds to a total strain energy of 694.5 kJ/mol. Attaching energetic group to the cubane skeleton opens the door to high- (higher-)energy density materials. For oxidizers, groups to be attached are nitro, nitrato, nitramino, or difluoroamino groups. The melting point of tetranitrocubane is above 543 K (270 °C). The density of tetranitromethane is 1.814 g/cm³.

The numbering of substituents on cubane may be a little confusing at first glance. The numbering of substituent sites is illustrated in Figure 4. It seems the numbering goes clockwise on the front face in positions 1 through 4, then moves from 4 to the back face, starting with 5, and continues clockwise all the way to position no. 8.

Highly nitrated cubanes are predicted to be very dense materials with great potential for explosives and propellants. Unfortunately, strained hydrocarbon nitro

Figure 4: Numbering of substituent sites in cubane.

derivatives cannot generally be prepared directly, e.g., by nitration of the parent hydrocarbons, because the stressed cage structures do not survive the harsh reaction conditions. Very good summaries of polynitropolycyclic cage molecules including polynitrocubanes and polynitroadamantanes are presented in [272] and in [273–275]. Cubane, cubylcubane, and nitrocubanes were included in a summary on energetic materials and their molecular structures [276]. See also [277–279]. The successful synthesis of nitrocubanes has opened new paths for the development of other energetic materials, including ammonium dinitramide [280–284].

10.1.1 Density of Nitrocubanes

The density of nitrocubanes increases with increasing number of nitro groups attached to the cube (Table 20). The correlation between theoretically predicted and experimentally measured density is pretty good until four or five nitro groups are attached, but the predicted density for octanitrocubane is much higher than the best density measured for octanitrocubane to date. It is interesting to follow the increase in density of cubane with increasing substitution of hydrogens by nitro groups and to compare predicted with measured densities [285]. Similar calculations were performed for nitroadamantane. A similar table was found in another source, Table 21.

Table 20: Density of four nitrocubanes.

Compound	Density, measured g/cm ³	Density, calculated g/cm ³
Cubane	1.29	1.37
1,3-Dinitrocubane	1.65	1.74
1,4-Dinitrocubane	1.66	1.74
1,3,5-Trinitrocubane	1.74	1.84
1,3,5,7-Tetranitrocubane	1.814	1.92

Data source: [285]

Table 21: Density of cubane and five nitrocubanes.

Molecule	Density, calculated g/cm ³	Density, measured g/cm ³
Cubane	1.29	1.29
1,4-Dinitrocubane	1.66	1.66
1,3,5-Trinitrocubane	1.77	1.76
1,3,5,7-Tetranitrocubane	1.86	1.81
1,2,3,5,7-Pentanitrocubane	1.93	1.96
Octanitrocubane	2.13	1.98

Data source: [286]

The progressive nitrocubane substitution of hydrogen with nitro groups showed a pattern by which single nitro-substitutions starting from cubane lead ultimately to octanitrocubane. Of the 22 member species, densities have been experimentally measured for only 8, and these were used to estimate the densities of the other 14 members [287].

10.1.2 Thermodynamic Properties of Nitrocubanes

Ab initio molecular orbital (SCF) calculations were performed on cubane, tetraazacubane, and their nitro derivatives [288]. The group equivalent method was used to calculate strain energies. Such calculated values showed that the substitution of carbons by nitrogen atoms in the cubane cage increases the strain energy. Increasing nitro substitution beyond four has a similar effect and this is more pronounced in the tetraazacubane system.

The heats of formation for 21 polynitrocubane compounds were calculated using several semiempirical molecular orbital methods and for eight of 21 polynitrocubanes containing one to four nitro groups using a density functional theory method by means of designed isodesmic reactions [289, 290]. All 21 polynitrocubane compounds have high heats of formation, implying that they can be very powerful energetic materials. By comparing the results, a relationship between the heats of formation and molecular structures for polynitrocubanes could be established.

The theoretically predicted strain energy of cubane is 708 kJ/mol = 169.13 kcal/mol, which was in good agreement with an experimental value. The variation of strain energy with respect to the number of substituents was calculated for polynitrocubane and polydifluoroaminocubane and it increased slightly as up to four substituent groups were added to the cage skeleton [291]. On the contrary, the strain energy dramatically increased when the number of substituent groups increased from five up to eight. For polynitratocubane, the strain energy decreased slightly at the beginning then increased as the number of groups increased. For polyazidocubane, there were very small group effects on the strain energy. Among four types of substituent groups, the nitro group had the greatest

effect on the strain energy of the caged cubane skeleton. The calculated strain energy of octanitrocubane is 1076 kJ/mol = 257.20 kcal/mol, while that of octaazidocubane is 697 kJ/mol = 166.48 kcal/mol. The substituent groups withdraw electrons from the cubane, reducing the repulsion between C—C bonds. This relieves the strain of the skeleton for isomers with fewer substituents. Group repulsions increased sharply as more and more nitro, nitrato, and difluoroamino groups were attached to cubane, resulting in large strains of the skeleton.

The enthalpy of formation, crystal density, detonation velocity, and pressure for polynitrocubanes have been calculated using various theoretical methods [292]. It has been observed that for polynitrocubanes the introduction of $-\text{NH}_2$ groups onto the skeleton resulted in destabilization of the neighboring C—C bonds on the skeleton. The C—C and C— NO_2 bonds of octanitrocubane were stronger than those of partly nitrated cubanes, implying that the shock stability of octanitrocubane should be superior to that of partly nitro-substituted cubanes. For polynitrocubanes the calculated crystal density was within 0.07 g/cm³ of the experimental crystal density, being more accurate than by the group additivity method. The detonation velocity, the detonation pressure, and the energy output all increased from tetranitrocubane to octanitrocubane. The detonation velocity and detonation pressure of octanitrocubane were predicted to reach 9.58 km/s and 60 GPa, respectively. The energy output of octanitrocubane is about 80% larger than that of HMX.

Calculations of enthalpies of formation of polynitrocubanes using density functional theory indicated that ΔH_f first decreased (number of nitro substituents $m = 0-2$) and then increased ($m = 4-8$) with each additional nitro group introduced into the cubane skeleton [293]. The enthalpy of formation of octanitrocubane in the vapor state was predicted to be +808 kJ/mol. The Gibbs free energy of formation increased by about 40–60 kJ/mol with each nitro group added to the cubane when the substituent number was fewer than four, then increased by about 100–110 kJ/mol with each additional group attached to the cubic skeleton. Both the detonation velocity and the pressure for polynitrocubanes increased as the number of substituents was increased. Other sources gave the enthalpy of formation of solid octanitrocubane as +98.9 kJ/mol.

Thermochemical calculations were conducted on the parent unsubstituted tetrahedrane and cubane hydrocarbons, and a list of 20 mono- and poly-functionalized derivatives with azo, **nitro**, and peroxy explosophoric substituents [294]. The high, mass-normalized gas-phase enthalpies of formation for both the tetrahedrane and cubane derivatives exceeded those of well-established primary and secondary (RDX and HMX) explosives by up to an order of magnitude.

10.1.3 Molecular Structure of Nitrocubanes

The structures of 1,4-dinitro-, 1,3,5-trinitro-, 1,3,5,7-tetranitro-, 1,2,3,5,7-pentanitro-, 1,2,3,4,5,7-hexanitro-, 1,2,3,4,5,6,8-heptanitro-, and octanitro-cubane had been reported prior to 2003 [295]; however, the structure of the simplest member of this series, nitrocubane (mononitrocubane), was reported later [296]. Nitrocubane

crystallized in orthorhombic crystals, space group *Pnma*, with cell dimensions $a = 17.507(5) \text{ \AA}$, $b = 6.584(2) \text{ \AA}$, and $c = 5.832(2) \text{ \AA}$, with four molecules in the unit cell and an X-ray density of 1.453 g/cm^3 .

Charge distributions in nitro derivatives of cubane, $\text{C}_8\text{H}_{8-n}(\text{NO}_2)_n$ ($n = 1-8$) have been derived employing *ab initio* Hartree–Fock and hybrid density functional theory methods [297]. The electron-rich regions around the oxygen atoms of the nitro group get smaller with increasing number of nitro groups in the series. Within different isomers of nitrocubane, the lowest energy isomers engender large electron-rich regions relative to the other isomers, which has been supported by the shallow electron density minima near oxygen atoms of nitro groups. The electrostatic potential at the center of the cube (cage critical point) on the other hand increased from mono- to octa-nitrocubane. The successive replacement of cubyl hydrogens by NO_2 groups pushes the added electrons along a cube with an increase of curvature of the C–C bonds. The electron density at the bond critical point and the curvature of the C–C bonds in a cubanoid increased from mono- to octa-nitrocubane. Heats of formation increased with increased destabilization in the nitrocubane isomers.

The impact sensitivity of some alkyl nitrates and cubane derivatives can be correlated with their heat of explosion and chemical structure [298]. These correlations revealed ways to reduce the explosion hazard in the handling of these compounds.

10.1.4 Thermal Stability of Nitrocubanes

It has been suggested that the higher decomposition temperatures of some nitrocubanes, which are higher than those of the parent hydrocarbon, may be due to the fact that nitro groups withdraw electrons from the skeleton and thus stabilize the system. The onset of exotherm temperatures of several nitrocubanes are listed in Table 22.

Quantum mechanical calculations were used to determine the structural and energetic characteristics of polynitrocubanes $\text{C}_8\text{H}_{8-n}(\text{NO}_2)_n$, where $n = 1-8$ [299]. Comparing minimum heights of the energy barriers to the decay of metastable clusters, it was shown that nitro groups destabilize the cubic carbon skeleton. For octanitrocubane the temperature dependence of the characteristic decay time at temperatures 500–1000 K and activation energy and frequency factor of the Arrhenius equation were calculated.

Table 22: Thermal stability of nitrocubanes

Compound	DSC onset temperature	
	K	°C
1,4-Dinitrocubane	530	257
1,3,5-Trinitrocubane	540	267
1,3,5,7-Tetranitrocubane	550	277

Data source: [286]

High-order electronic structure calculations with empirical bond additivity corrections have been applied to thermal decomposition reactions of nitrocubanes and validated by comparisons of different levels of theory and by comparison with experiments [300]. These methods provide a cost-effective means of obtaining thermal rate data and show promise of being applicable to reactions involving large polyatomic molecules important in nitrocubane decomposition.

10.1.5 Predicted Explosive Performance of Nitrocubanes

Thermodynamic studies of several polynitropolycyclic systems including nitrocubanes were used to calculate the explosive performance of such compounds [301]. The detonation velocity, the detonation pressure, and the energy output all increased from tetranitrocubane to octanitrocubane. The detonation velocity and pressure of octanitrocubane were predicted to reach 9.58 km/s and 60 GPa, respectively. The energy output of octanitrocubane is about 80% larger than that of HMX.

Other calculations predicted a theoretical detonation velocity of octanitrocubane of 9900 m/s, while the same method predicted for hexanitrobenzene, HMX, and CL-20 the detonation velocities of 9500, 9100, and 9200 m/s, respectively [302].

10.2 Mononitrocubane

Mononitrocubane was synthesized via a 14-step synthesis starting with cyclopentanone [303]. The heat of decomposition and the onset temperature of thermal decomposition were determined.

10.3 Dinitrocubane

1,4-Dinitrocubane can be prepared by first converting cubane-1,4-dicarboxylic acid to 1,4-aminocubane and then oxidizing that with *m*-chloroperbenzoic acid [304]. The yield in the last stage was 40%. This material did not decompose below its melting point of 533 K = 260 °C, which is higher than the start of decomposition (473 K = 200 °C) of the unsubstituted cubane hydrocarbon itself. Introduction of two nitro groups seemed to stabilize the molecule.

1,4-Dinitrocubane crystals undergo phase changes at high pressures. The pressure–temperature reaction phase diagram for 1,4-dinitrocubane was determined using optical polarizing microscopy and FTIR spectroscopy in conjunction with a high-pressure diamond anvil cell and the ruby fluorescence method of pressure measurement [305]. The phase transformation is of an order–disorder type.

10.4 Trinitrocubane

Systematic substitution of hydrogens on the cubane nucleus with nitro groups, illustrated with the examples of 1,3,5-trinitrocubane and 1,3,5,7-tetranitrocubane, has given us a better understanding of the effects of progressive substitution on thermal stability and enthalpy of formation of such molecules [306].

10.5 Tetranitrocubane

A precursor in the preparation of tetranitrocubane is cubane-1,2,4,7-tetracarboxylic acid [307]. 1,3,5,7-Tetranitrocubane is an extraordinary material. It is a crystalline solid with a very high density (1.814 g/cm³). Although a very energetic compound, it is kinetically quite stable, not melting until 543 K (270 °C), and then only with decomposition, not detonation.

The hydrogen atoms in the beta position to the nitro groups are very acidic. The measured pK_a is 21, at least 20 powers of ten more acidic than cubane itself. Much of this enhanced acidity must be the result of the tremendous inductive electron-withdrawing power of the nitro groups stabilizing the anion. Salts of tetranitrocubane are readily formed and can be used in the synthesis of higher nitrated cubanes. The sodium salt of tetranitrocubane has been used to convert tetranitrocubane to pentanitrocubane. Pentanitrocubane is about a thousand times more acidic than tetranitrocubane, and its sodium salt was converted in turn by interfacial nitration to hexanitrocubane, an even more acidic material.

Nitro groups on alternate corners of cubane enhance the acidity of cubyl hydrogen ($pK_a \sim 21$) and provide sufficient activation for ready anion formation. The sodium salt of 1,3,5,7-tetranitrocubane reacted easily with electrophiles and allowed the synthesis of more highly substituted cubanes [308, 309]. Dinitrogen tetroxide reacted with the anion of tetranitrocubane to give 1,2,3,5,7-pentanitrocubane, the first cubane to contain vicinal nitro groups. The reaction probably involved oxidation of the anion to the corresponding radical. Similarly, the anion of pentanitrocubane was used to prepare 1,2,3,4,5,7-hexanitrocubane, the most highly nitrated cubane known as of 1997. The crystal structures of both penta- and hexanitrocubane were examined by single-crystal XRD.

The push–pull electron effect of nitro and amino groups at opposite ends of a molecule leads to a significant stabilization of the dinitrodiaminoethene molecule (see Section “Physical Properties of FOX-7”). It was hoped that a similar effect would lead to stabilization of aminonitrocubanes and aminonitroazacubanes. *Ab initio* self-consistent-field molecular orbital computational studies of the structures and bond orders (as measures of relative bond strengths) of nitro and aminonitro derivatives of cubane and some azacubanes showed that the NO₂ group had a conformation-dependent effect on relative bond strengths [310, 311]. When the plane of the nitro

group was perpendicular to that of an endocyclic bond, that bond was weakened. An aza nitrogen adjacent to C—NO₂, however, eliminated the bond-weakening effect due to a “perpendicular” nitro group, except when a C—NH₂ was also adjacent to the C—NO₂. The NH₂ group had a direction-specific bond-weakening effect on one endocyclic bond. The influences of NO₂ and NH₂ were essentially independent; when these substituents were on adjacent carbons the effects were reinforcing. Thus, the combination of a “perpendicular” NO₂ and an NH₂ on adjacent carbons in cubane and azacubanes produced a marked bond weakening.

1,3,5,7-Tetranitrocubane is a crystalline solid with high density (1.814 g/cm³) and is kinetically quite stable, not melting until 543 K (270 °C). The full non-rigid group behavior of NO₂ groups in tetranitrocubane and octanitrocubane was modeled with computational methods [312, 313].

If four carbons in the cubane cube are replaced by nitrogens, and four hydrogens are replaced by nitro groups, one obtains a new class of energetic compound, tetranitrotetraazacubanes [314]. Density functional theory and molecular mechanics computations predicted a density of 2,4,6,8-tetranitro-1,3,5,7-tetraazacubane (TNTAC) of about 2.12 g/cm³, a detonation velocity of 10.42 km/s, and detonation pressure of 52.82 GPa, all of which are higher than those of octanitrocubane.

10.6 Pentanitrocubane

Pentanitrocubane is the first example of a nitrocubane with nitro groups on adjacent carbons. Nitro groups on alternate corners of cubane enhance the acidity of cubyl hydrogen and provide sufficient activation for ready anion formation. The sodium salt of 1,3,5,7-tetranitrocubane can react easily with electrophiles and can lead to yet more highly substituted cubanes, like carbomethoxy- and (trimethylsilyl)-tetranitrocubane. Anions from these species are also easily formed and are useful for further substitution on the cubane skeleton. Dinitrogen tetroxide reacted with the anion of tetranitrocubane to give 1,2,3,5,7-pentanitrocubane, the first cubane to contain vicinal nitro groups [315]. Similarly, the anion of pentanitrocubane was used to prepare 1,2,3,4,5,7-hexanitrocubane, the most highly nitrated cubane made to that date.

10.7 Hexanitrocubane

In the hexanitrocubane structure, C₈H₂N₆O₁₂, the H atoms participate in short hydrogen-bonding contacts to the nitro O atoms in adjoining molecules, thus linking molecules into a two-dimensional sheet in the *bc* plane [316]. In addition, the O···O contacts in hexanitrocubane are shorter than van der Waals contact distances. The shortest of these, with a length of 2.766(3) Å, involve the O atoms of one of the attached nitro groups. These contacts involve molecules in an extended two-dimensional sheet parallel to the *ab* plane.

10.8 Heptanitrocubane

Heptanitrocubane was an intermediate in the synthesis of the long-sought octanitrocubane [317]. In the first synthesis of heptanitrocubane, four of the eight nitro groups were introduced by functional group modification and three more by low-temperature N_2O_4 nitration of sequentially formed polynitrocubyl anions.

Heptanitrocubane is easier to make than octanitrocubane. Heptanitrocubane has a very high density (2.028 g/cm^3). Surprisingly, the predicted density of heptanitrocubane is higher than that of octanitrocubane. It has a calculated heat of formation only about 6% less than octanitrocubane.

Heptanitrocubane forms colorless crystals when its solution in fuming nitric acid is diluted with sulfuric acid. Single-crystal X-ray analysis confirmed the assigned structure and provided an accurate density at 294 K (21 °C) of 2.028 g/cm^3 , impressively high for a CHNO compound. Although octanitrocubane received more interest due to its symmetry and predicted explosive performance, heptanitrocubane is easier to make than octanitrocubane. It may prove to be a more powerful explosive and/or monopropellant as it is denser, has a calculated heat of formation only about 6% less than octanitrocubane, and will produce some lighter molecular mass gaseous products as it is not perfectly oxygen balanced.

10.9 Octanitrocubane

Octanitrocubane, $\text{C}_8(\text{NO}_2)_8$, ONC, CAS RN [99393-63-2], is one of a unique group of strongly oxidizing chemicals called “nitrocarbons” that consist only of a carbon skeleton and nitro groups. Other compounds in this group with similar structures are TNM, hexanitroethane, hexanitrobenzene, or decanitrobiphenyl. There is even a book devoted specifically to these types of chemicals [110]. Octanitrocubane has a perfect oxygen balance of 0% for combustion of all carbon to carbon dioxide. It is unlikely that octanitrocubane will ever be used as a rocket propellant. It is mentioned here only as an example of energetic material synthesis driven to the extreme.

10.9.1 Preparation of Octanitrocubane

In the first synthesis of octanitrocubane, four of the eight nitro groups were introduced by functional group modification, three more by low-temperature N_2O_4 nitration of sequentially formed polynitrocubyl anions, and the eighth and last by nitrosation of the heptanitrocubyl anion followed by ozonation [273, 317, 318]. Addition of excess NOCl to a solution of the lithium salt of heptanitrocubane in dichloromethane at 195 K (−78 °C) followed by ozonation at 195 K (−78 °C) gave the long-sought octanitrocubane in 45–55% yield. Octanitrocubane was the sixth known nitrocarbon discovered and the first new one to be made in the 18 years preceding 2000.

At this time, octanitrocubane is still very difficult to prepare and available only in gram quantities for further characterization. Other methods of synthesis are sought. One particularly enticing approach recognizes the fact that four molecules of dinitroacetylene are a stoichiometric (atom-by-atom) equivalent of one molecule of octanitrocubane. Perhaps octanitrocubane can be made directly by tetramerization of dinitroacetylene. Unfortunately, dinitroacetylene is not yet a known compound and it is most likely very unstable.

10.9.2 Physical Properties of Octanitrocubane

Based on XRD, the calculated theoretical density of octanitrocubane is 2.10 g/cm^3 for the most stable polymorph of octanitrocubane. Other sources report a density of 1.979 g/cm^3 [319].

Octanitrocubane is a stable, white solid, somewhat soluble in hexane and readily soluble in polar organics, but often crystallized with water of hydration, even from non-aqueous solvents. The density was measured at 1.979 g/cm^3 which, though high, was at the lower end of the original range of theoretical predictions. Taking into account the available data on polynitrocubane crystal structure, calculations predicted a density of 2.135 or 2.123 g/cm^3 for the most stable polymorph of octanitrocubane. Many nitro compounds have multiple polymorphs of remarkably different density. Octanitrocubane sublimes unchanged at atmospheric pressure at 473 K (200 °C).

In examining the IR spectra of octanitrocubane, a new type of vibration (quartic concerted torsional mode, abbreviated as QCTM) has been predicted for octanitrocubane which has been attributed to the rotation of the NO_2 group.

10.9.2.1 Thermodynamic Properties of Octanitrocubane

As of 2002, the most recently published calculated value for the heat of formation of solid octanitrocubane was 594 kJ/mol . It was predicted that the combustion of octanitrocubane to carbon dioxide and nitrogen would release 3475 kJ/mol .

One calculated value for the heat of formation of solid octanitrocubane, $(\text{CNO}_2)_8$, is 594 kJ/mol , corresponding to 74 kJ/mol per (CNO_2) increment. For comparison, the highest calculated ΔH_f of solid hexanitrobenzene, $(\text{CNO}_2)_6$, one of the most energetic explosives known, is about 200 kJ/mol , corresponding to 33 kJ/mol per (CNO_2) moiety, less than half that of octanitrocubane. The energy content of hexanitrobenzene is lowered by the stabilizing resonance energy of the aromatic ring. The energy content of octanitrocubane is increased by the strain energy of its unique carbon skeleton [318].

The molecular geometries, IR vibrational spectra, and thermodynamic properties of octanitrocubane were calculated using a density functional theory method [320]. The heat of formation of octanitrocubane in the gas phase is 726.47 kJ/mol . The sublimation enthalpy, density, and heat of formation for octanitrocubane crystals were calculated as 220.63 kJ/mol , 2.189 g/cm^3 , and 505.84 kJ/mol , respectively. The predicted detonation velocity and detonation pressure of octanitrocubane were

10.26 mm/ μ s and 520.86 kbar, respectively. Calculations showed that the pyrolysis initiation reaction of octanitrocubane is to initially form a diradical by the single C—C bond breaking in the cube. The second C—C bond breaking results in formation of a nitrocyclooctatetraene. The calculated activation energy for the pyrolysis initiation reaction of octanitrocubane was 155.30 kJ/mol.

10.9.2.2 Molecular Structure of Octanitrocubane

The molecular structure of octanitrocubane is that of a box with eight —NO₂ handles on it (Figure 5).

Figure 5: Molecular structure of octanitrocubane.

Ab initio molecular orbital and density functional theory calculations on isodesmic disproportionation reactions of nitrated cubanes indicated that the repulsion between nitro groups on adjacent carbons in octanitrocubane is surprisingly small and that the energy required for successive substitutions of nitro groups on the cubane frame diminishes progressively with increasing substitution [321]. As a consequence of the inductive effects of the nitro groups on one another, the negative charge on the oxygens also decreases with increasing substitution, reducing the magnitudes of the Coulomb repulsion between nearest-neighbor nitro groups. The O...O interactions remained very small throughout 180° rotations about the C—NO₂ bonds, a process that was computed to be nearly barrierless.

Homodesmotic reactions and isodesmotic reactions were designed for the computation of strain energies for a series of cubane derivatives [291]. The strain energy value of cubane itself is 708 kJ/mol = 169.13 kcal/mol for a homodesmotic reaction, which is in good agreement with the experimental value. The strain energy values of polynitrocubane and polydifluoroaminocubane increased slightly as up to four substituent groups were added to the cage skeleton. On the contrary, the strain energies dramatically increased when the number of substituent groups, *m*, increased from five up to eight. For polynitratocubane, the strain energies decreased slightly at the beginning, then increased as the number of nitro groups increased. For polyazidocubane, there were very small group effects on the strain energies. Among four types of substituent groups considered in this study, the nitro group had greatest effect on the

strain energy of the caged cubane skeleton. The calculated strain energy value of octanitrocubane was $1076 \text{ kJ/mol} = 257.2 \text{ kcal/mol}$, while that of octaazidocubane was $696.6 \text{ kJ/mol} = 166.5 \text{ kcal/mol}$.

Cubanes with *N,N*-dinitroamino instead of nitro pendants have not yet been synthesized, but their molecular structure and energy potential has already been calculated. The heats of formation, the detonation velocity, and the detonation pressure of poly-*N,N*-dinitroaminocubanes were calculated by density function theory (DFT) methods [322]. The results showed that all cubane derivatives have positive heats of formation, which increase with increasing number of dinitroamino groups attached to the cube. The detonation performances of polydinitroaminocubanes were estimated by the Kamlet–Jacobs equation, and the results indicated that most cubane derivatives have good detonation performance, better than RDX or HMX.

10.9.3 Experimental Study of Octanitrocubane Thermal Decomposition

Because octanitrocubane is difficult to obtain, there are only few reports on experimental determination of thermal stability and thermodynamic properties. As of 2005, the onset of thermal decomposition of tetranitrocubane was reported as 550 K (277°C), but the onset of thermal decomposition of octanitrocubane was still unknown. In the literature, there are ten times more theoretical than experimental studies on the thermal stability and bond strength of octanitrocubane.

10.9.4 Computations of Octanitrocubane Thermal Decomposition

The explosive properties of octanitrocubane had been predicted by quantum mechanical computational chemistry methods many years before even the precursors in its synthesis had been made. The question is whether the thermal decomposition of octanitrocubane starts with a nitro–nitrite isomerization or with C–C bond rupture yielding a biradical intermediate.

A semi-empirical molecular orbital theory was used to calculate some possible decomposition pathways of nitrocubanes and nitroazacubanes [323]. The calculations indicated that the most likely reaction in cubane, dinitrocubane, tetranitrocubane, hexanitrocubane, and octanitrocubane thermolysis involves an initial opening of a cube C–C bond, followed by an opening of the C–C bond of the seven-bonded intermediate to form a nitrocyclooctatetraene. The reaction is exothermic. Similar reaction pathways were predicted for nitroazacubanes.

The initial pyrolysis process of condensed-phase octanitrocubane at high temperature was investigated using ReaxFF reactive molecular dynamics simulation [324]. The computation showed that it is the C–C bond of the octanitrocubane cage skeleton structure that breaks first, then the octanitrocubane cage skeleton structure is gradually destroyed, and small molecules such as NO_2 and O_2 occur only afterwards. The simulation identified three different damage pathways of the cage skeleton. The main products of octanitrocubane thermal decomposition at high temperature were pre-

dicted to be NO_2 , O_2 , CO_2 , N_2 , NO_3 , NO , CNO , and CO , of which N_2 and CO_2 are the ultimate products. The composition of decomposition products depends on temperature.

Bond dissociation energies and activation barriers for primary decomposition reactions for a series of caged polynitroamino and polynitro compounds, such as octanitrocubane, CL-20, and hexanitro derivatives of adamantane, were predicted using domain-localized pair natural orbital modifications of coupled-cluster techniques [325]. For all species studied, $\text{C}-\text{NO}_2$ or $\text{N}-\text{NO}_2$ radical decomposition channels dominated over molecular scission. The gas-phase enthalpy of formation of octanitrocubane was predicted to be $+704 \pm 6 \text{ kJ/mol}$ ($+168.2 \pm 1.5 \text{ kcal/mol}$).

10.9.5 Explosive Performance of Octanitrocubane

We are mostly interested in octanitrocubane as a propellant ingredient and not as an explosive, so calculations of its detonation parameters are of less interest, but we list them here nevertheless, such as [326]. One theoretical estimation of the detonation velocity for octanitrocubane gave 9900 m/s. This is higher than experimental values for hexanitrobenzene of 9500 m/s or HMX of 9100 m/s or CL-20 with 9200 m/s.

10.9.6 Predicted Propellant Performance of Octanitrocubane

The theoretical performance of a propellant containing octanitrocubane was calculated for sea-level operation under standard conditions ($p_c/p_e = 70:1$) [327]. Replacing ammonium perchlorate with octanitrocubane in an HTPB-bonded propellant increased the specific impulse by 125 N s kg^{-1} . A nitrocellulose/glycerol trinitrate/ONC smokeless composite modified double-base propellant had a specific impulse of 2545 N s kg^{-1} , and a GAP/ONC/RDX smokeless propellant had a specific impulse of over 2600 N s kg^{-1} .

10.9.7 Nitrosocubanes

Nitrosocubanes would have a lower oxygen content than nitrocubanes and may be more difficult to synthesize. Octanitrosocubane should have thermodynamic properties similar to octanitrocubane. Optimized structures, vibrational frequencies, enthalpies of formation, and specific enthalpies of combustion for a series of nitrosocubanes ranging from mononitrosocubane to octanitrosocubane have been predicted by computational chemistry [328].

10.10 Nitroadamantanes

The direct nitration of adamantane with concentrated nitric acid in glacial acetic acid at elevated temperature and pressure produced a mix of 1-nitro-, 1,3-dinitro-, and 1,3,5-

trinitroadamantanes, the last in very low yield [329]. 1-Nitroadamantane and 1,3-dinitroadamantane can be prepared by direct nitration of adamantane with acetic acid and nitric acid in a pressure reactor [330]. 1-Nitroadamantane melts at 431.6–432.1 K (158.5–159 °C) in a sealed capillary. 1,3-Dinitroadamantane melts at 487–488 K (214–215 °C).

The photochemical reaction of N_2O_5 with adamantane yielded only mononitroadamantane.

The oxidation of 1-aminoadamantane with permanganate has been used for the synthesis of 1-nitroadamantane [331, 332]. Another compound prepared during that time was azoadamantane.

It was hoped that 1,3,5,7-tetranitroadamantane, $\text{C}_{10}\text{H}_{12}\text{N}_4\text{O}_8$, Figure 6, would rival HMX, CL-20, or some of the other caged high-energy compounds in explosive performance and thermal stability. However, despite such optimism, only a few other polynitroadamantanes have been reported since 1980. It appears that there is no significant advantage of adding more nitro groups to the caged structure.

Figure 6: Molecular structure of 1,3,5,7-tetranitroadamantane.

1,3,5,7-Tetranitroadamantane, with its high melting point of ca. 623 K (350 °C, with incipient decomposition), can be of value as a heat-resistant explosive but not necessarily an ingredient for rocket propellants. 1,3,5,7-tetranitroadamantane can be prepared by oxidation of 1,3,5,7-tetraaminoadamantane with permanganate [333, 334], where 1,3,5,7-tetraaminoadamantane was obtained by hydrolysis of 1,3,5,7-tetraacetamidoadamantane as an intermediate. The heat of combustion was 16.5 kJ/g (3.952 kcal/g) compared to 15.7 kJ/g (3.750 kcal/g) for TNT.

A modification of this synthesis route led to some improvements, in particular the yield of 1,3,5,7-tetraacetamidoadamantane could be improved from 51 to 95% [335]. The total yield of 1,3,5,7-tetranitroadamantane from adamantane was raised to 18% compared to 8% reported in the literature.

Nitroadamantanes bearing *gem*-dinitro groups on bridge carbons were synthesized from oximinoadamantanes by reaction with nitric acid, or, alternatively, by reaction with aqueous hypobromite, reduction of the intermediate *gem*-bromonitroadamantanes, and oxidative nitration [336]. The presence of two *gem*-dinitro groups in 2,2,6,6-tetranitroadamantane greatly enhanced the density,

which was now 1.75 g/cm^3 , compared to a related open, uncaged structure, 2,2,6,6-tetranitrobicyclo[3.3.1]nonane, with a density of only 1.45 g/cm^3 .

2,2-Dinitroadamantane and 2,2,6,6-tetranitroadamantane had been synthesized by oxidation of the corresponding oximes which were made from the oxo carbonyl ke-toadamantane. Similar attempts to make 2,2,4,4-tetranitroadamantane failed, apparently due to proximity effects. A different procedure replaced one carbonyl at a time and was more successful [337].

In view of the difficulties associated with the oxidation of vicinal amino groups, an alternate route of synthesis by way of an oxime was chosen for 1,2,2-trinitroadamantane [338].

The heats of formation of a series of polynitroadamantanes were calculated systematically using a density functional theory method without breaking the adamantane skeleton (i.e., choosing adamantane as a reference compound) [339]. The relative stability of these compounds was illustrated according to the results calculated by heat of formation, the energy gaps between the frontier orbitals, and the bond order of C–NO₂.

2,2,4,4-Tetranitroadamantane was synthesized using adamantan-2-one as raw material [340]. First, the synthesis conditions of an important intermediate 4,4-(ethylenedioxy)adamantan-2-one were optimized. The *gem*-nitration of 4,4-(ethylenedioxy)adamantan-2-one oxime was then performed using N₂O₅. The optimum reaction conditions of the reaction were: methylene chloride as solvent, the molar ratio of 4,4-(ethylenedioxy)adamantan-2-one oxime to N₂O₅ was 1:3, reaction temperature 318 K (45 °C), and reaction time 30 min with yields of 52.3%. The overall yield of 2,2,4,4-tetranitroadamantane was 14.2%, which was 1.9-times better than that reported in the literature.

1,3,5,7-Tetranitroadamantane crystallized in a tetragonal crystal shape, space group $P4_21c$, with cell parameters of $a = b = 7.874(2) \text{ \AA}$, $c = 10.552(2) \text{ \AA}$, $V = 654.2(2) \text{ \AA}^3$, $Z = 2$, and $\rho_{\text{XRD}} = 1.605 \text{ g/cm}^3$ [341]. The nitro groups were rotated approximately 15° from a symmetrical eclipsed position. The crystal symmetry was identical to that of the low-temperature form of unsubstituted adamantane. The melting point was 634–636 K, which is very high!

A review of adamantane, polynitroadamantanes, and polynitroazaadamantanes was given in [342]. The CAS RN of hexanitroadamantane is [143850-71-9].

A study of molecular mass/density and oxygen content/sensitivity relationships of polynitroadamantanes and their aliphatic counterparts showed that densities, sensitivities, and detonation properties of polynitroadamantanes obtained/calculated were similar to those of standard high explosives [343]. Some of them might be better than TNT and similar to PETN or RDX. Their non-caged aliphatic counterparts with a similar number of nitro groups and gross formulas may be exceptionally sensitive, which excludes them from possible use as high explosives or propellants.

Crystals of 1-amino-3,5,7-trinitroadamantane, C₁₀H₁₄N₄O₆, crystallize in monoclinic crystals, space group $P2_1/n$, with cell parameters of $a = 14.089 \text{ \AA}$, $b = 13.806 \text{ \AA}$,

$c = 14.414 \text{ \AA}$, $\beta = 118.86^\circ$, $V = 2455 \text{ \AA}^3$, and $Z = 8$, and the X-ray density is $\rho_{\text{XRD}} = 1.55 \text{ g/cm}^3$ [344].

The heats of combustion and enthalpies of vaporization for oxygen-containing, nitro-, and nitrate-derivatives of adamantane were measured by precision calorimetry methods [345]. On the basis of these data, the enthalpies of formation in the standard state and in the gaseous phase were calculated. Table 23 gives a summary of the heats of combustion, heats of formation, and heats of sublimation of adamantane, nitroadamantanes, and adamantyl nitrates.

Table 23: Thermodynamic properties of adamantane, nitroadamantanes, and adamantyl nitrates.

Compound	Heat of combustion kJ/mol	Heat of formation, solid kJ/mol	Heat of sublimation kJ/mol	Heat of formation, gas kJ/mol
Adamantane	6028.3 ± 1.2	193.3 ± 1.2	58.2 ± 1.2	135.1 ± 1.7
Adamantanone	5615.1 ± 1.2	319.7 ± 1.2	76.1 ± 1.5	243.6 ± 1.9
1-Adamantanol	5832.5 ± 2.0	389.1 ± 2.0	82.0 ± 1.5	307.1 ± 2.5
1-Nitroadamantane	5822.0 ± 2.2	256.9 ± 2.0	81.2 ± 2.0	175.7 ± 2.8
1,3-Dinitroadamantane	5622.0 ± 1.2	313.4 ± 1.2	103.8 ± 1.5	209.6 ± 1.9
2,2-Dinitroadamantane	5685.2 ± 2.2	250.6 ± 2.2	89.1 ± 1.5	161.5 ± 2.7
1-Adamantyl nitrate	5773.9 ± 2.0	305.0 ± 2.0	79.9 ± 1.5	225.1 ± 2.5
1,3-Adamantanediyl dinitrate	5522.0 ± 2.0	413.8 ± 2.0	105.9 ± 1.7	307.9 ± 2.6

Data source: [345]

Predicted IR spectra of polynitroadamantanes were obtained by vibrational analysis based on fully optimized molecular geometries and electronic structures and compared to experimental results [346, 347]. Thermodynamic properties were then calculated based on these IR frequencies and the principles of statistic thermodynamics. The dependence of thermodynamic functions on temperature and the number of nitro groups was examined. It was found that the nitro groups obeyed a good group additivity rule. As an example of this method, a fully optimized molecular geometry and electronic structure of 1,3,5,7-tetranitroadamantane supplemented by predicted IR spectra was used to calculate thermodynamic properties by statistic thermodynamics [348]. A potential pyrolysis mechanism was identified via a semi-empirical MO method, providing the transition state and activation energy, and concluding that rupture of the C—NO₂ bond is the first step. Additionally, the predicted detonation velocity and detonation pressure were evaluated by means of the Kamlet–Jacobs equation based on the calculated theoretical density and heat of formation. The synthesis of decanitroadamantane remains an elusive target. Similar calculations were performed for polynitrohexaazaadamantanes [349].

While adamantane can be nitrated directly with nitric acid/acetic acid at high temperature/pressure and with photolyzed N₂O₅, it was predicted by theory that nitration

with NO₂ will encounter a barrier obstacle. Density functional theory and semi-empirical molecular orbital methods were employed to study the reaction mechanism of the nitration of adamantane with NO₂ [350]. The calculated results showed that the H atom in adamantane cannot be directly substituted with NO₂.

The molecular crystal packings of three polynitroadamantanes with 8–10 –NO₂ groups were assigned among the seven most probable space groups using a molecular mechanics computational method [351]. Thereafter, *ab initio* periodic calculations and density of states calculations showed that the C–N bond was the most likely trigger bond of polynitroadamantane thermal decomposition.

Sixteen different polynitroadamantanes were designed by computer and their properties were studied by predicting IR spectra, thermodynamic properties, thermal stability, and detonation performance [352]. It was noted that the frequencies of symmetric stretching vibrations of the nitro group in polynitroadamantanes showed a bathochromic shift with an increasing number of nitro groups. However, the frequencies of asymmetric stretching vibrations had a contrary trend. The heat of formation, detonation velocity, and pressure of 16 polynitroadamantanes were estimated by the Kamlet–Jacobs formula. The predicted thermal stabilities of polynitroadamantanes were studied by the bond dissociation energy and an energy level difference calculation. The number of nitro groups was in direct proportion to improved detonation properties, but was in inverse proportion to the stability of polynitroadamantanes. Among the polynitroadamantanes having the same number of nitro groups, those in which the nitro group linked with a methylene group had better properties than those in which the nitro group linked with a methyldiyne group.

2,2-Dinitroadamantane and 2,2,4,4,8,8-hexanitroadamantane were analyzed by HPLC using acetonitrile/water (80/20 volume ratio) as a mobile phase, which allowed exceptionally good separation on these two analytes when the flow rate was 1.0 mL/min [353]. Results showed that the detection limit, linear range, linear correlation coefficient, and precision of 2,2-dinitroadamantane are 0.003 mg/mL, 0.005–1.000 mg/mL, 0.9987, and 1.382%, respectively. Correspondingly, the same parameters for 2,2,4,4,8,8-hexanitroadamantane were 0.001 mg/mL, 0.005–1.000 mg/mL, 0.9984, and 1.300%, respectively.

10.11 Nitrofullerenes

Is it possible to make nitro-buckminsterfullerene C₆₀ with 1 to 60 nitro groups? Apparently some nitrofullerenes have been reported, but it is unlikely that there will ever be sufficient material available to use it as a rocket propellant [354–357]. The all-hydrocarbon caged skeleton analog to CL-20, decorated with nitro groups, would still be a very energetic molecule, even without the nitramine linkages.

Prolonged treatment of C_{60} in benzene with very high concentrations of N_2O_4 formed a new polynitro [62]fullerene whose composition was determined as $C_{60}(NO_2)_{14}$ by TGA [358]. The compound was unstable and deflagrated above 443 K (170 °C) when heated under nitrogen or in air with the release of a considerable amount of heat as observed by DTA and DSC. The decomposition steps of $C_{60}(NO_2)_{14}$ were followed by TGA coupled with FTIR. At the deflagration point, $C_{60}(NO_2)_{14}$ released a mixture of nitrogen oxides: NO_2 and NO with minor amounts of N_2O . The deflagration left a residue of oxidized carbon which upon heating released CO_2 and CO and at 973 K (700 °C) was converted to a carbonaceous matter free from residual oxygenated groups, showing also the presence of small amounts of C_{60} fullerene.

11 Nitroalkanols

Up until this section of the chapter on “Nitroaliphatic Compounds” we have summarized information on aliphatic nitro compounds that did not contain any other substituents on the carbon skeleton other than nitro groups. In the following there are several sections where the aliphatic compound contains other substituents such as hydroxy, oxo, amino, nitramino, azido, azo, and other substituent groups attached to the alkyl skeleton. The question was whether these compounds should be discussed here under nitro compounds or in the chapters “Alcohols,” “Aliphatic Amines,” and “Nitramines”. At the moment, we have done both, which results in some duplication and overlap of different sections.

11.1 2-Nitroethanol

The lowest member in the family of nitroalkanols, nitromethanol, O_2NCH_2OH , is not stable. 2-Nitroethanol, $O_2NCH_2CH_2OH$, is somewhat more stable but still hazardous. 2-Nitroethanol freezes at 193 K (−80 °C) and boils at 467 K (194 °C) at sea level pressure or at 375–378 K (102–105 °C) at 14 mm Hg. The density of 2-nitroethanol is 1.270 g/cm³. The heat of combustion of 2-nitroethanol at constant volume is 1154 kJ/mol = 275.8 kcal/mol [359, 360]. The CAS RN of 2-nitroethanol is [625-48-9]. 2-Nitroethanol can be prepared by condensation of nitromethane and formaldehyde [361].

The synthesis of 2-nitroethanol was used as an example for continuous flow synthesis in a microreactor [362]. Flow synthesis has the advantage that only a small amount of reactants are at the high temperature and the reaction mixture is quickly chilled after it leaves the reaction zone.

2-Nitroethanol has been patented as a monopropellant, as a separate co-injected monopropellant or an intimate mixture with hydrazine [363].

Certain nitroalkanols where the nitro group is attached to a secondary or tertiary carbon atom are used as disinfectants and bactericides because they act as formalde-

hyde donors. Some nitroalkanols such as glycerol dinitrate are the result of incomplete nitration of polyols. Other nitroalkanols are useful intermediates in the synthesis of other energetic compounds.

11.2 2,2,2-Trinitroethanol

The most useful compound in this group is 2,2,2-trinitroethanol, $C_2H_3N_3O_7$, $(O_2N)_3CCH_2OH$, $M = 181.07$ g/mol, because it is an intermediate in the synthesis of a large number of energetic compounds with 2,2,2-trinitroethyl groups which have very desirable properties. One example are the esters of 2,2,2-trinitroethanol with acrylic acid or methyl acrylic acid, which can be polymerized to form energetic binders. Trinitroethanol can be reacted with different moieties through the Mannich reaction, such as ammonia, aliphatic amines, hydrazine, and even urea as the amine component in order to synthesize the corresponding trinitroethyl derivatives. Examples include 3-(*N*-2,2,2-trinitroethyl)amino-1,2,4-triazole, 4-(*N*-2,2,2-trinitroethyl)amino-1,2,4-triazole, 4-(*N*-Nitro-*N*-(2,2,2-trinitroethyl))amino-1,2,4-triazole, and bis(2,2,2-trinitroethyl) amine [364]. Physical, explosive performance, and sensitivity properties of ten 2,2,2-trinitroethyl derivatives, mostly those with triazole rings, were compared to those of TNT, RDX, and HMX.

2,2,2-Trinitroethanol can easily be synthesized by reaction of nitroform with paraformaldehyde [365]. The method was later improved. For preparation of 2,2,2-trinitroethanol with carbon tetrachloride as a solvent, the mixture of trinitromethane and paraformaldehyde, a turbid solution/suspension, was heated with stirring for 3 h at 333–338 K (60–65 °C) and then at reflux for 30 min [366, 367]. Concentrating the solution and cooling in the refrigerator gave trinitroethanol in the form of long needles with m.p. 345 K = 72 °C. The overall yield was 80%. This melting point is lower than the melting point reported by other sources and must be due to an impure product. Trinitroethyl alcohol is an unstable, crystalline compound. Its thermal initiation temperature is about 393 K (120 °C). It can be distilled (with precautions) and boils at 376 K = 103 °C at 14 mm Hg. 2,2,2-Trinitroethanol is a relatively strong acid, $K_a = 4.3 \times 10^{-3}$. The high acidity can be explained by the strong electron drawing force exerted by the three nitro groups. See also [368]. Trinitroethanol at 200 K forms orthorhombic crystals, space group $P2_1/c$ (no.14) with $a = 6.1218(4)$ Å, $b = 18.8120(12)$ Å, $c = 11.7391(8)$ Å, $\alpha = 90^\circ$, $\beta = 104.997(4)^\circ$, $\gamma = 90^\circ$, $V = 1305.87(15)$ Å³, $Z = 8$, and $\rho = 1.842$ g/cm³.

Similar results were obtained in a more recent investigation which showed that 2,2,2-trinitroethanol crystallized in monoclinic crystals with space group $P2_1/c$, with cell parameters of $a = 6.1242(4)$ Å, $b = 18.8223(7)$ Å, $c = 11.7446(4)$ Å, $\beta = 104.962(3)^\circ$, $V = 1308.14(11)$ Å³, $Z = 8$, $\rho = 1.839$ g/cm³ [369]. The structure displayed intra-molecular O—H···O hydrogen bonds as well as inter-molecular O—H···O and C—H···O hydrogen

bonding; the O—H...O hydrogen bonds, forming rings and dipolar nitro–nitro interactions, account for the high density of 1.839 g/cm³.

Physicochemical properties of β -nitro alcohols and some of their derivatives are listed in Table 24.

Table 24: Physicochemical properties of β -nitro alcohols and their derivatives.

Compound	Boiling point (at P, Pa)	Boiling point (at P, mm Hg)	Melting point		Refractive index n_D^{20}	Density ρ_4^{20} g/cm ³
	K	°C	K	°C		
2-Nitroethanol	336 (66)	63 (0.5)	—	—	1.443	1.296
2,2,2-Trinitroethanol	355 (266)	82 (2)	345	72	—	—
2-Nitropropanol	372 (1329)	99 (10)	—	—	1.4379	1.1841

Data source: [370]

Other polynitroalkanols and polynitroalkanediols of interest as plasticizers or intermediates for the synthesis of energetic plasticizers include 2,2-dinitro-1,3-propanediol [371], 3,3-dinitropentane-1,5-diol, and 4,4-dinitroheptane-1,7-diol [372].

Other energetic derivatives of trinitroethanol include tris(2,2,2-trinitroethyl)borate, B[OCH₂C(NO₂)₃]₃ with a density of 1.524 g/cm³; tetrakis(2,2,2-trinitroethyl)orthocarbonate, C[O—CH₂—C(NO₂)₃]₄ with a density of 1.84 g/cm³ and a decomposition temperature of 436 K (163 °C), TNEOC; 2,2,2-trinitroethyl carbamate, (O₂N)₃CCH₂O—CO—NH₂, TNC with a density of 1.839 g/cm³; bis(2,2,2-trinitroethyl) oxalate, (O₂N)₃CCH₂O—CO—CO—O—CH₂—C(NO₂)₃, BTNEO, with a density of 1.884 g/cm³; and 2,2,2-trinitroethyl nitrocarbamate, (O₂N)₃CCH₂O—CO—NH—NO₂, TNC-NO₂ [373–375].

Infrared absorption spectra of β -nitroalcohols in solution showed predominantly monomeric hydroxyl —OH absorption and single nitro —NO₂ stretching bands, indicative of non-bonded species, but some bonding due to inter-molecular hydrogen bonds probably occurs in the solid state [376].

2,2-Dinitro-1-methoxypropane was used as a model compound whose structure resembled that of more complex nitro plasticizer components [377]. A decomposition

mechanism was proposed for 2,2-dinitro-1-methoxypropane based on existing decomposition mechanisms for similar nitro compounds. The proposed decomposition mechanism began with HONO elimination and leads to intermediates that can produce CO, CO₂, NO, and N₂O gases. A high-temperature mechanism involved NO₂ scission.

2,2,2-Trinitroethanol, 2,2-dinitropropanol, and 2,2-dinitropropanediol-1,3 underwent enantiotropic transitions at 312.4, 282.2, and 341.1 K (39.3, 9.1, and 68.0 °C), respectively. All of the high-temperature forms were cubic and possessed properties of the plastic crystalline state. DSC was used to measure the heats of fusion and the heats of transition. The heats of transition were 2,2,2-trinitroethanol: 18.0 kJ/mol = 4.3 kcal/mol; 2,2-dinitropropanol: 15.1 kJ/mol = 3.6 kcal/mol; and 2,2-dinitropropanediol-1,3: 21.3 kJ/mol = 5.1 kcal/mol [378]. The difference between the heat of transition of each nitroalkanol and its corresponding nitroalkane has been interpreted as a measure of hydrogen bonding energy in the low-temperature form of the nitroalkanol.

In addition to 2,2,2-trinitroethanol with three terminal nitro groups, its homologue 3,3,3-trinitropropanol has also been considered as a building block for energetic materials. Compared with the well-established 2,2,2-trinitroethyl group in the chemistry of energetic materials, the 3,3,3-trinitropropyl group is less investigated regarding its chemical and energetic properties. Investigations on the syntheses of several compounds containing the 3,3,3-trinitropropyl group were performed and their properties compared with the 2,2,2-trinitroethyl group [379]. All materials were characterized by DSC, single-crystal XRD, and the sensitivities towards impact, friction, and electrostatic discharge were tested using a drop hammer, a friction tester, and an ESD tester.

Other nitroalkanols once evaluated as propellant ingredients are 1,1,1-trinitro-3-hydroxybutanol, C₄H₇N₃O₈, (O₂N)₃CCHOHCH₂CH₂OH, *M* = 225.11 g/mol, with an enthalpy of formation of -373 cal/g = -83.97 kcal/mol and 1,1,1-trinitro-2-hydroxybutanol, C₄H₇N₃O₈, (O₂N)₃CCH₂CHOHCH₂OH, with an enthalpy of formation of -373 cal/g = -83.97 kcal/mol [97]. These would most likely be esterized with acrylic acid to serve as energetic binders. The heat of combustion at constant volume of tris(hydroxymethyl)nitromethane is 2125 kJ/mol = 507.8 kcal/mol [359].

The mono-trinitroethyl esters of nitramino glycine have a tendency to form dimers [380]. Some of these compounds have a positive oxygen balance and are potentially suitable as rocket propellants.

The di-ester of trinitroethanol with nitraminodiacetic acid, 2-[carboxymethyl (nitro)amino]acetic acid, 2,2'-(nitroimino)diacetic acid, C₄H₆N₂O₆, is a high-energy compound suitable as a rocket propellant ingredient [381]. It has an X-ray density of 1.84 g/cm³ at 155 K (-118 °C) and a decomposition point of 453 K (180 °C).

Nitraminodiacetic acid bis(2,2,2-trinitroethyl) ester

11.3 Fluorodinitro Alcohols

The molecular mass of 2-fluoro-2,2-dinitroethanol, $\text{F}(\text{NO}_2)_2\text{CCH}_2\text{OH}$, $\text{C}_2\text{H}_3\text{O}_5\text{N}_2\text{F}_1$, is 154.05 g/mol. The enthalpy of formation is $-741 \text{ cal/g} = -114 \text{ kcal/mol} = -478 \text{ kJ/mol}$ [97]. Fluorodinitroalkanols can be prepared by three different methods: **(1)** fluorination of 1,1-dinitrocarbanion salts with perchloryl fluoride, **(2)** aqueous fluorination of 1,1-dinitrocarbanion salts, **(3)** reactions of fluorotrinitromethane with various nucleophiles. The reaction of 30% H_2O_2 , formaldehyde, methanol, and fluorotrinitromethane gives 2-fluoro-2,2-dinitroethanol [382].

Another method for preparation of 2-fluoro-2,2-dinitroethanol is the reaction of potassium hydroxide in water and methanol to which 2,2-dinitropropanediol-1,3 in methanol was added dropwise, the temperature being kept below $285 \text{ K} = 12^\circ\text{C}$ [383]. The precipitated potassium 2,2-dinitroethanol was separated from solvent and washed twice with methanol and once with ether. To the residue after evaporating the ether, dimethylformamide was then added, the mixture cooled to $288 \text{ K} = 15^\circ\text{C}$, and perchloryl fluoride bubbled in at this temperature. The mixture was acidified with sulfuric acid and the dimethylformamide removed under vacuum. The product was extracted with ether, the ether removed, and the residue distilled in vacuum where it boiled at $328\text{--}330 \text{ K} = 55\text{--}57^\circ\text{C}$ at 1.7 mm Hg. The yield of 2-fluoro-2,2-dinitroethanol thus obtained was 25% of the theoretical yield. The product was colorless, had a slightly nitrous odor, and froze at $282\text{--}283 \text{ K} = 9\text{--}10^\circ\text{C}$. The utility of this compound was demonstrated by preparing several esters with orthocarbonic acid and nitrocarbonic acids.

The direct aqueous fluorination of potassium dinitroethanolate gave fluoro-dinitroethanol, which was further characterized as the formal [384]. Fluorination of nitroform under these conditions gave fluorotrinitromethane. The reaction of sulfur tetrafluoride with 2,2-dinitropropanol, 2,2-dinitro-1,3-propanediol, and trinitroethanol gave 1-fluoro-2,2-dinitropropane, 1,3-difluoro-2,2-dinitropropane, and 2,2,2-trinitrofluoroethane, respectively. The reaction of tetrafluorohydrazine with the sodium salts of 1,1-dinitroethane and 1,1-dinitrobutane gave the dinitrodifluoroalkanes. The product of the former was very sensitive to impact.

Similar to 2,2,2-trinitroethanol, 2-fluoro-2,2-dinitroethanol can be used for the synthesis of a wide range of energetic compounds [385–387]. 2-Fluoro-2,2-dinitroethanol is a useful intermediate for the synthesis of fluorodinitroethyl amines and esters [388]. See also [389].

12 Fluorodinitroalkyl Amines

Fluorodinitroalkyl amines will be discussed in detail in *Encyclopedia of Liquid Fuels* chapter “Aliphatic Amines.” They can be prepared from fluorodinitroethanol or fluordinitromethane. The enthalpy of formation of bis(2-fluoro-2,2-dinitroethyl)amine (BFDNA) is -531 kJ/mol ($-126.952 \text{ kcal/mol}$) [390].

13 Higher Mono- and Polynitroethers

It was the objective of several decades' worth of synthetic efforts to synthesize oxygen-rich compounds containing several nitro and/or nitroxy groups as replacements for glycerin trinitrate as a plasticizer in double-base propellants. Such replacements had to be thermally more stable, less volatile than glycerin trinitrate, and have a better oxygen balance. The oxygen balance of polynitro alkane compounds can be improved by introducing oxygen links (ether groups) into the molecule and/or replacing some of the hydrogen by fluoro groups.

Two ether linkages can be introduced into a molecule by reacting polynitroalkans with formaldehyde or acetaldehyde, forming formals and acetals.

13.1 Polynitroalkyl Ethers

2-Nitroethyl ethyl ether, $\text{O}_2\text{NCH}_2\text{CH}_2\text{OC}_2\text{H}_5$, is a colorless liquid having a sharp odor and a boiling point of 451 K (178°C) at sea level pressure or $345 \text{ K} = 72^\circ\text{C}$ at 12 mm Hg reduced pressure. The density is 1.079 g/cm^3 at $298 \text{ K} = 25^\circ\text{C}$ and the refractive index is $n_D^{25} = 1.4160$. 2-Nitroethyl ethyl ether can be prepared by reaction of 1,2-dinitroethane or 2-nitroethyl nitrate with ethanol in refluxing ethanol where the top of the condenser is kept warm enough that all low-boiling ethyl nitrite is removed soon after it has formed [391].

2,2-Dinitroethyl ethyl ether, $(\text{O}_2\text{N})_2\text{HCH}_2\text{C}-\text{O}-\text{C}_2\text{H}_5$, is a colorless oil with a boiling point of 373 K (100°) at 11 mm Hg reduced pressure, which can be prepared by reacting trinitroethane with potassium ethoxide.

Attempts to synthesize trinitromethyl methyl ether or trimethylsilyl trinitromethyl ether or trinitromethyl *tert*-butyl ether were not successful [392].

Bis(2,2,2-trinitroethyl)formal, also known as $[(\text{NO}_2)_3\text{CCH}_2\text{O}]_2\text{CH}_2$, TEFO, can be used as plasticizer [393]. The onset of thermal decomposition of trinitromethyl or trinitroethyl ethers depends on the molecule they are attached to. A study of rapidly heated thermal decomposition of $[(\text{NO}_2)_3\text{CCH}_2\text{O}]_x\text{CH}_4-x$, $x = 2-4$ (TEFO, TNEOF, TNEOC, respectively) by rapid-scan FTIR spectroscopy with temperature profiling as a function of pressure showed that they melted 40 °C or more below the decomposition point when rapidly heated (70–200 °C/s) [394]. The first detected thermolysis step was homolysis of a few C–NO₂ bonds per molecule liberating NO₂(G). The temperature at which this occurred at 15 psi Ar was TEFO (145 °C) TNEOF (180 °C) TNEOC (200 °C).

Nitromethyl nitroxymethyl ether, nitromethoxy methanol nitrate, O₂NO–CH₂–O–CH₂–NO₂, is a colorless oily liquid with a density of 1.50 g/cm³, a boiling point of 321 K at 2 kPa (48 °C at 15 mm Hg), and which is an energetic explosive. Its shock sensitivity and thermal stability are worse than that of ethylene glycol dinitrate (EGDN) and it is also more volatile. The lead block indentation of nitromethyl nitroxymethyl ether is 420 cm³ which is 93% of that of GTN. The synthesis of nitromethyl nitroxymethyl ether starts with formaldehyde and hydrogen chloride to prepare bis-chloromethyl ether which is then nitrated with mixed acid.

13.2 Bis(2-fluoro-2,2-Dinitroethyl) Formal (FEFO)

There may be some overlap in the information provided in this book on difluoroamino compounds and nitro compounds. If one requires a complete evaluation of those mixed substituent energetic compounds, one will need to read both sections. The group of energetic polynitroethers includes bis(2-fluoro-2,2-dinitroethyl) formal (FEFO) and 1,3-bis(2-fluoro-2,2-dinitroethoxy)-2,2-bis(difluoroamino) propane (SYEP).

FEFO

Both FEFO and SYEP are energetic plasticizers that are used in formulating solid propellants and plastic-bonded explosives. The most thoroughly investigated fluoro-dinitroalkyl formal is bis(2-fluoro-2,2-dinitroethyl)formal, also known as bis(2-fluoro-2,2-dinitroethoxy)methane, 1,1'-[methylenebis(oxy)]bis(2-fluoro-2,2-dinitroethane), $\text{FC}(\text{NO}_2)_2\text{CH}_2\text{OCH}_2\text{OCH}_2\text{C}(\text{NO}_2)_2\text{F}$, $\text{C}_5\text{H}_6\text{N}_4\text{O}_{10}\text{F}_2$, FEFO, CAS RN [17003-79-1].

FEFO has a high energy content but is quite volatile and toxic and has a relatively high melting point. FEFO has an oxygen balance of +14.88% assuming combustion to CO and -9.99% assuming combustion to CO₂. Its drop-weight impact sensitivity is $H_{50} = 26$ to 28 cm (2 kg weight) compared to 15 cm for glycerin trinitrate. FEFO is hydrolytically unstable.

Both bis(2-fluoro-2,2-dinitroethyl) formal (FEFO) and bis(2,2-dinitropropyl) formal (BDNPF) are used as energetic plasticizers in explosive and propellant compositions.

13.2.1 Preparation of FEFO

An efficient three-step process to prepare FEFO was developed and scaled up to production plant equipment in 100–1000 gallon reactors [395]. Starting with the elemental fluorination of nitroform, high yields and purities of the process intermediates and final product were realized.

The purity of FEFO can be verified by gas chromatography [396]. Gas chromatographic analysis can detect small concentrations of FEFO [397]. Purity requirements and methods of analysis of FEFO are covered by Military Specification MIL-SPEC RM-253202.

13.2.2 Physical Properties of FEFO

FEFO is a liquid explosive with a density of 1.60 g/cm³. The heat of formation of FEFO is -690 kJ/mol = -165 kcal/mol. The properties of FEFO are listed in Table 25.

Table 25: Properties of FEFO.

Property	SI units	Other units	Source
Molecular mass	320.12 g/mol	3.124 mol/kg	
Density at 293 K	1.59 g/cm ³	—	Rocketdyne data sheet
Density at 293 K	1.607 g/cm ³	—	[398]
Melting point	287 K	14 °C	Rocketdyne data sheet
Melting point	284.5–286.1 K	11.3–12.9 °C	[398]
Boiling point	393–397 K at 40 Pa	120–124 °C at 0.3 mm Hg	[398]
Vapor pressure	28.5 mPa at 298 K	0.000214 mm Hg at 25 °C	[398]
Compressibility	4.03 mm ² /N	4.04 × 10 ⁻¹¹ cm ² /dyn	[399]
Velocity of sound	1.25 km/s	—	[399]
Heat of formation ΔH_f^{298}	-745 kJ/mol	-178 kcal/mol	[398]
Heat of formation ΔH_f^{298}	-746 kJ/mol	-557 cal/g = -178 kcal/mol	[97]
Heat capacity	1.05 J g ⁻¹ K ⁻¹ at 200 K	0.25 cal g ⁻¹ °C ⁻¹ at -73 °C	[398]

13.2.3 Reactions of FEFO

Compatibility between FEFO and a number of organic and metallic materials has been evaluated at 295 and 347 K (22 and 74 °C) for up to 8 months [400, 401]. The 300 series stainless steels, Al 6061-T6, and Monel 400 showed evidence of surface attack (oxidation or pitting). Polished gold coupons became discolored. Platinum, iridium, titanium, tantalum, and Ta-10% W showed little evidence of reaction. Kalrez, fluorinated ethylene propylene (FEP), and perfluoroalkoxy alkane polymer (PFA) were compatible. Among the organic materials, the perfluorinated materials showed only slight interaction with the FEFO while polyethylene, polyester, and Aclar[®] were attacked by the liquid. These interactions manifested themselves in changes in color, net weight gain, and mechanical properties. The changes were aggravated by higher temperatures.

13.2.3.1 Thermal Decomposition of FEFO

The thermal decomposition of three energetic plasticizers containing the formal group, FEFO, TEFO, and DITEFO have been studied by rapid-scan IR spectroscopy [402]. The five *gem*-trinitro compounds studied to that date all displayed a transition from decomposition to deflagration according to the gas products evolved during the first second of rapid thermolysis. FEFO was the first compound without a *gem*-trinitro group to exhibit this transition in the same experiment. Under directly comparable conditions, fluoro dinitro compounds were confirmed to be more thermally stable than the analogous *gem*-trinitro compounds.

In the DSC at a heating rate of 10 °C/min., the first onset of exotherm was at 482 K (209 °C) and it peaked at 518 K (245 °C). The theoretical considerations which led to the initial synthesis of compounds containing the $\text{FC}(\text{NO}_2)_2$ group indicated that the enhanced sensitivity and thermal stability properties of 1-fluoro-1,1-dinitro compounds relative to corresponding 1,1,1-trinitro compounds are primarily due to reduced steric hindrance, which allows free rotation of the nitro groups about the C—NO₂ bonds, such free rotation acting in effect as an internal energy sink [403]. When steric hindrance to free rotation is reintroduced, as when the $\text{FC}(\text{NO}_2)_2$ group is α or β to another *gem*-dinitro function or β to an aromatic ring, the sensitivity and thermal stability properties become relatively poor.

The simultaneous TGA-modulated beam mass spectrometry (STMBMS) technique has been applied to measure the vapor pressures and evaluate the thermal decomposition chemistry of two energetic plasticizers, bis(2-fluoro-2,2-dinitroethyl)formal (FEFO) and bis(2-fluoro-2,2-dinitroethyl)difluoroformal (DFF) [404]. The resulting heat of vaporization (ΔH_{vap}) and vapor pressure at 298 K (25 °C) were 84.9 ± 0.8 kJ/mol (20.3 ± 0.2 kcal/mol) and 0.05 Pa (0.4 ± 0.1 $\mu\text{m Hg}$) for FEFO, and 72.4 ± 0.8 kJ/mol (17.3 ± 0.2 kcal/mol) and 0.068 Pa (5.1 ± 1.1 m Hg) for DFF. The thermal decomposition of FEFO indicated that there are six major pyrolysis pathways where FEFO initially decomposed at 423 K (150 °C) by rearrangement of the nitro group to the nitrite group,

followed by loss of NO. Some NO₂ was also formed at 443 K (170 °C). Between 473 and 573 K (200–300 °C), further pyrolysis occurred. In one pathway, the FEFO backbone remained intact and a high-molecular-weight product was formed. The other three pathways involved scission of the FEFO backbone, one yielding CO₂ (possibly N₂O), one yielding CH₂O and CO, and one yielding C₃H₂NOF.

13.2.4 Toxicity of FEFO

Experience gained by 13 known users of FEFO was documented in interview transcripts with several appendices [405]. The first of these, Appendix A, was a survey on worker experiences with FEFO. Appendix B was a toxicology screening study of FEFO. Appendix C was a material safety datasheet on FEFO. Appendices D and E were formerly classified documents. Appendix F was a file on medical treatment associated with FEFO exposure. FEFO was shown to be quite biologically active by all observers. It was also stated that by correct use of strict industrial hygiene controls it can be used in large amounts with relative safety.

13.2.5 Explosive Sensitivity of FEFO

A series of detonation experiments was carried out on FEFO to determine the non-reactive equation of state and initiation sensitivity to one-dimensional shock loading [406]. The material was found to be extremely insensitive, requiring a shock pressure of approximately 13.0 GPa to initiate it. Pressure records indicated that the build-up to detonation may occur within the FEFO and not at the impactor–sample interface as is often assumed. In addition, it was found that the compression vs. detonation induction time behavior between FEFO and three nitroalkanes were approximately the same, although the shock pressure thresholds were quite different.

The shock initiation of FEFO was studied using a two-stage gas gun with magnetic gauges to measure the compression wave profiles during a shock-to-detonation transition [407]. Unreacted Hugoniot data, time-to-detonation (overtake) measurements, and reactive wave profiles were obtained from each experiment. FEFO was found to initiate by the homogeneous initiation model, similar to other liquid explosives (nitromethane, isopropyl nitrate). FEFO is very insensitive, with about the same shock sensitivity as the TATB-based explosive PBX9502 and cast TNT.

It was hoped that replacement of some of the hydrogen in polynitroalkanes would reduce the sensitivity of the compounds. Therefore, the impact sensitivities of several compounds with and without hydrogen substitution by fluorine were compared. The desensitization of explosive compounds has been studied by the synthesis and testing of analogs of selected molecular structures in which part of the hydrogen was replaced by fluorine. The objectives were to demonstrate whether or not “chemical desensitization” could be achieved with fluorine in specific positions and groupings, to infer from the results how the fluorine affected the initiation process and to permit the de-

sign and synthesis of high-energy and relatively insensitive compounds [408]. Methods of synthesis and physical properties of several dozen nitro-fluoro compounds were described in this report. Desensitization of the ether, bis(fluorodinitroethoxy)ethane, was obtained by substituting the four hydrogens with fluorine; and results from impact and shock initiation tests showed that the fluorine analog was definitely less sensitive and was as energetic as the hydrogen compound. In the card gap test, the positive initiation of FEFO to high velocity detonation (HVD) occurred at 80–85 cards, and even with a very thick spacer of 1500 cards the material would still explode in LVD mode (100 cards corresponds to approximately 1 inch). The impact sensitivity of FEFO in a Technoproducts Dropweight Tester was 6 kg-cm. For comparison, the impact sensitivity of ethyl nitrate was 1–2 kg-cm. In the Bureau of Mines test apparatus with a no. 12 tool, the impact sensitivity (50% point) of FEFO was 28 cm with a 5-kg weight.

In a U-tube adiabatic compression sensitivity test apparatus with variable, preselected push pressure and constant bubble size, the push pressure required to explode FEFO was higher than that of GTN, EGDN, or DEGDN, but below that of *N,N*-bis(β -nitroxyethyl)nitramine (DINA) or 2-nitroxyethyl *n*-butyl nitramine (BuNENA) [409].

13.2.6 Explosive Performance of FEFO

The heat of detonation and the products of detonation of FEFO were compared to those of HMX and TNT [410, 411]. The heats of detonation determined in a calorimeter ranged from 4581 to 6192 J/g (1095 to 1480 cal/g).

The detonation velocity of FEFO is 7861 m/s [399]. The critical diameter for propagation of detonation is in the order of millimeters.

13.2.7 FEFO Mixtures

Bis-(2-fluoro-2,2-dinitroethoxy)-(1-fluoro-1,1-dinitro-2-propoxy)methane, also known as M-FDNEOF, $(\text{O}_2\text{N})_2\text{CFCH}(\text{CH}_3)\text{OCH}[\text{OCH}_2\text{CF}(\text{NO}_2)_2]_2$, is a plasticizer that can be used in combination with FEFO [412]. M-FDNEOF is a low melting solid (m.p. 320–322 K = 47–49 °C) with a calculated liquid density at 298 K = 25 °C of 1.60 g/cm³. Its heat of formation was estimated to be –1314 kJ/mol = –314 kcal/mol. M-FDNEOF is almost equal to FEFO in energy content (calculated detonation pressure, 243 kbar vs. 248 kbar for FEFO). Therefore, the addition of M-FDNEOF to FEFO does not significantly change the energy content of the system. M-FDNEOF is miscible with FEFO in all proportions, and forms a binary eutectic with FEFO in the approximate weight ratio of FEFO:M-FDNEOF = 70:30, m.p. 278 K = +5 °C. Thus, the addition of M-FDNEOF, particularly in this amount, to FEFO results in a significant decrease of the plasticizer melting point. This will impart improved low-temperature properties to propellants or plastic-bonded explosives using the plasticizer mixture in place of FEFO alone.

13.3 Other 2-Fluoro-2,2-Dinitroethyl Ethers and Formals

2,2-Dinitropropyl-2-fluoro-2,2-dinitroethyl formal can be prepared by the following steps: (1) reacting one mol of formaldehyde with two mols of 2,2-dinitropropanol in the presence of an excess of aluminum chloride to produce chloromethyl 2,2-dinitropropyl ether; (2) isolating the product chloromethyl 2,2-dinitropropyl ether; (3) reacting one mol of 2-fluoro-2,2-dinitroethanol with chloromethyl 2,2-dinitropropyl ether in the presence of titanium tetrachloride to produce 2,2-dinitropropyl 2-fluoro-2,2-dinitroethyl formal; and (4) isolating the product 2,2-dinitropropyl 2-fluoro-2,2-dinitroethyl formal [413].

Another compound taking advantage of the fluorodinitromethyl energetic pendant is bis(2-fluoro-2,2-dinitroethoxy)acetonitrile, $\text{N}\equiv\text{C}-\text{CH}[\text{OCH}_2\text{CF}(\text{NO}_2)_2]_2$, CYANO-FEFO [414]. The use of bis(2-fluoro-2,2-dinitroethoxy)acetonitrile as a co-plasticizer for bis(2-fluoro-2,2-dinitroethyl)formal (FEFO) provides several advantages over the use of FEFO by itself. CYANO-FEFO is useful as a co-plasticizer with bis(2-fluoro-2,2-dinitroethyl)formal in energetic plasticizer mixtures for plastic-bonded explosives. CYANO-FEFO is a low melting solid (m.p. 314–315 K = 41–42 °C) with a liquid density at 296 K = 23 °C of 1.62 g/cm³. Its heat of formation was estimated to be -732 kJ/mol = -175 kcal/mol, and the calculated detonation pressure was 244 kbar.

Bis(2-fluoro-2,2-dinitroethyl) ether can be prepared by reacting a stable intermediate bis(2,2-dinitro-3-hydroxypropyl) ether with a fluorinating agent in the presence of a base [415]. In order to prepare bis(2-fluoro-2,2-dinitroethyl) ether, the intermediate bis(2,2-dinitro-3-hydroxypropyl) ether in a solvent in the presence of a base is contacted with the fluorinating agent (elemental fluorine diluted with nitrogen in a ratio of between 0.5:1.5 to 1.5:0.5 or gaseous perchloryl fluoride) at 0–5 °C until slightly acidic and the original yellow color begins to disappear.

Polynitroethyl ethers can be prepared by nitration of the corresponding oximes. Nitroethers prepared in this way which are of potential interest as propellant ingredients are 2-fluoro-2,2-dinitroethyl-2,2-dinitroethyl ether, bis(2-fluoro-2,2-dinitroethyl) ether, (2-fluoro-2,2-dinitroethoxy)-2,2-dinitropropyl formal, and 1,3-bis(2-fluoro-2,2-dinitroethoxy)-2,2-dinitropropane [416]. It is not clear whether any of these have advantages over the established energetic plasticizers like BDNPA/F.

13.4 Other Trinitroethyl Ethers and Formals

2,2,2-Trinitroethyl 2-nitroxyethyl ether, $(\text{O}_2\text{N})_3\text{CCH}_2\text{OCH}_2\text{CH}_2\text{ONO}_2$, TNEN, can be prepared by the following reaction sequence: **(1)** reacting one mol of potassium nitroform with one mol of chloromethyl 2-bromoethyl ether to produce the intermediate 2,2,2-trinitroethyl 2-bromoethyl ether; **(2)** reacting the 2,2,2-trinitroethyl 2-bromoethyl ether with silver nitrate to form 2,2,2-trinitroethyl 2-nitroxyethyl ether [417]. The energy

content of TNEN is between that of glycerin trinitrate (GTN) and butanetriol trinitrate (BTTN). The melting point of TNEN is lower than that of nitroglycerin (284 K = 11 °C vs. 287 K = 14 °C) and TNEN is less volatile and thus less toxic than nitroglycerin. The TNEN density is 1.55 g/cm³. 2,2,2-Trinitroethyl 2-nitroxyethyl ether is useful as an energetic plasticizer.

14 Nitroalkyl Esters

2,2,2-Trinitroethanol is an intermediate in the synthesis of a large number of energetic compounds with 2,2,2-trinitroethyl groups which have very desirable properties. One example is the esters of 2,2,2-trinitroethanol with acrylic acid or methyl acrylic acid which can be polymerized to form energetic binders.

Another ester, 2,2-dinitro-1,3-propanediol-diformate, $\text{HOOCCH}_2\text{—C(NO}_2)_2\text{—CH}_2\text{COOH}$, is a low-sensitivity, energetic plasticizer that is useful in explosive and propellant compositions. 2,2-Dinitro-1,3-propanediol diformate can be synthesized by the esterification of 2,2-dinitro-1,3-propanediol [418]. 2,2-Dinitro-1,3-propanediol-diformate can be made by reacting 2,2-dinitro-1,3-propanediol with acetic formic anhydride in the presence of pyridine and a solvent. The properties of 2,2-dinitro-1,3-propanediol-diformate are listed in Table 26.

Table 26: Properties of 2,2-dinitro-1,3-propanediol-diformate

Property	SI units	Other units
ΔH_f (heat of formation)	−609 kJ/mol (measured)	−145.5 kcal/mol (measured)
Density	1.474 kg/dm ³	1.474 g/cm ³
Boiling point	about 363 K @ 6.6 Pa	about 90 °C @ 0.05 mmHg
Vacuum thermal stability (100 °C/48 h)	1.602 cm ³	—
Freezing point	Below 210 K	Below −60 °C
ABL impact sensitivity	0.11 m	11 cm
ABL friction sensitivity	3.52 kN @ 2.43 m/s	800 lbf @ 8 ft/s
ESD sensitivity, unconfined	More than 8J	—
ESD sensitivity, confined	8J	—
SBAT onset	395 K	122 °C (252 °F)
Card gap sensitivity	NO GO @ 0 cards	—
DSC onset temperature	562 K	289 °C

Data source: [418]

Dinitropropyl acrylate, $\text{C}_6\text{H}_8\text{N}_2\text{O}_6$, molecular mass = 204.14 g/mol, can be polymerized into an energetic binder. Its enthalpy of formation is −514 cal/g = −104.9 kcal/mol = 439 kJ/mol and its density is 1.304 g/cm³ = 0.0471 lb/in³ [97].

15 Nitroalkyl Formals and Acetals

Formals and acetals are dialkyl ethers with substituents on the alkyl groups and two oxygens linked to a central carbon atom.

15.1 Bis(2,2-dinitropropyl)formal

Bis(2,2-dinitropropyl)formal, also known as $C_7H_{12}N_4O_{10}$, bis(2,2-dinitropropoxy)-methane, $[H_3C-C(NO_2)_2-CH_2-O-]_2CH_2$, BDNPF, CAS RN [5917-61-3], $M = 312.21$ is sometimes used as a plasticizer by itself, but most often it is used in a mixture with bis(2,2-dinitropropyl)acetal (BDNPA) [419].

Bis(2,2-dinitropropyl)formal, BDNPF

BDNPF can be synthesized by the condensation reaction between 2,2-dinitropropanol and paraformaldehyde in methylene chloride.

The use of methylene chloride, an environmentally troublesome solvent, can be avoided by reacting 2,2-dinitropropanol at low temperature with a stoichiometric excess of formaldehyde in the presence of a protic acid catalyst, such as H_2SO_4 , HCl , H_3PO_4 , or HBr [420]. Although 2,2-dinitropropanol is not very soluble in water, solid 2,2-dinitropropanol is mixed with an excess of a formaldehyde source to form a reaction slurry. Addition of a small amount of hexane helps solubilize the solid reactants and BDNPF product and does not participate in the reaction. The formaldehyde source could be either s-trioxane or paraformaldehyde. To inhibit by-product formation, the reaction temperature is maintained from about 243 to 303 K (–30 to 30 °C). After completion of the reaction, the mixture is neutralized with caustic soda and the product is extracted with methyl *tert*-butyl ether. The yield is 60–70% based on the starting quantity of 2,2-dinitropropanol.

Bis(2,2-dinitropropyl)formal crystallizes as monoclinic crystals, space group $C2/c$, with the axis parameters $a = 23.330(3) \text{ \AA}$, $b = 6.207(3) \text{ \AA}$, $c = 10.009(6) \text{ \AA}$, $\beta = 109.60(3)^\circ$, $V = 1365.6(11) \text{ \AA}^3$, $Z = 4$ [421]. In the crystal structure, molecules are linked into chains running parallel to the b axis by inter-molecular $C-H \cdots O$ hydrogen bond interactions, which explains the high melting point of this compound.

Oral LD50 toxicity for rats of bis(2,2-dinitropropyl) formal, bis(2,2-dinitropropyl) acetal, and a 1 : 1 mixture of the two was 1920, 2918, and 1994 mg/kg, respectively [422]. An analysis of data suggested that acute toxicity of the two ingredients is additive.

These substances caused methemoglobinemia in a dose–effect relationship, and led to degenerative lesions in hepatocytes and epithelial cells of the renal proximal tubule but did not show any obvious irritating effect on the skin and eyes of rabbits. Consistent with the *Salmonella*/microsome assay, any of the three failed to increase chromosome aberrations and SCE frequency in mammalian cells.

15.2 Other Nitroalkyl Formals

Bis(2,2-dinitropropyl ethylene) formal (BDNPEF), a new *gem*-dinitro energetic plasticizer,

can be synthesized by aldol condensation of formaldehyde (trioxane) with 2,2-dinitropropanol and ethylene glycol with boron trifluoride etherate as the catalyst [423]. The yield was 23%. One of the by-products of this process was bis(2,2-dinitropropyl) formal (BDNPF) with 18% yield, which can be separated and also used as an energetic plasticizer. Compared to commercial nitro plasticizers, BDNPEF showed improved plasticization efficiency with a decrease in glass transition temperature (T_g) and viscosity of uncured glycidyl azide polymer (GAP) blends, as well as a substantial ability to plasticize GAP-based polyurethanes. The T_g of BDNPEF and BDNPF was 206.61 K = -66.54°C and 203.67 K = -69.48°C , respectively. BDNPEF was predicted to have a density of 1.499 g/cm^3 , heat of formation of $979\text{ kJ/mol} = 234\text{ kcal/mol}$, and impact sensitivity of 230 cm.

Based on calculations of fully optimized molecular geometric structures via a molecular orbital method, IR spectrum, heat of formation, and detonation performances of BDNPEF were predicted [424]. The bond dissociation energies and bond orders for the weakest bonds were analyzed to investigate the thermal stability. The results showed that the four N–NO₂ bond dissociation energies are nearly equal to each other with values of near 164 kJ/mol, which showed that this should be a stable compound. The detonation velocity and pressure were evaluated using Kamlet–Jacobs equations based on the theoretical density and condensed heat of formation. The crystal structure obtained by molecular mechanics belongs to a $P2_1$ space group, with lattice parameters $Z = 2$, $a = 13.8017\text{ \AA}$, $b = 13.4072\text{ \AA}$, $c = 5.5635\text{ \AA}$.

15.3 Bis(2,2-dinitropropyl)acetal

Bis(2,2-dinitropropyl)acetal, also known as $[\text{H}_3\text{C}-\text{C}(\text{NO}_2)_2-\text{CH}_2-\text{O}-]_2\text{CHCH}_3$, BDNPA, CAS RN [5108-69-0],

can be prepared by reaction of 2,2-dinitropropanol at low temperature with an acetaldehyde source in the presence of an acid catalyst, such as a Lewis acid catalyst or protic acid catalyst [425]. To inhibit by-product formation, the reaction temperature is maintained below 273 K. Upon completion of the reaction, the reaction solution is quenched with water and washed with an aqueous hydroxide solution. The hydroxide concentration should be sufficient to neutralize any acid formed during the quenching step and to solubilize unreacted 2,2-dinitropropanol as well as other aqueous soluble by-products in the reaction solution. The BDNPA product can be extracted with methyl *tert*-butyl ether. The solvent is evaporated to yield BDNPA. The BDNPA yield can be 50% of theoretical based on the starting quantity of 2,2-dinitropropanol. The density of BDNPA is 1.47 g/cm³.

15.4 Bis(2,2-dinitropropyl)acetal/Bis(2,2-dinitropropyl)formal Mixtures

The acronym for this widely used mixture is BDNPA/F.

Bis (2,2-dinitropropyl) formal (BDNPF) is an energetic plasticizer used in insensitive high-performance explosives and propellants. However, it has an inherent disadvantage in that it is a solid at room temperature such that it cannot be used by itself. Thus, to make it usable as a plasticizer, a eutectic mixture of BDNPF with its homologue is used, which is a liquid called BDNPA/F. The purity requirements and methods of analysis of BDNPA/F are described in Military Specification MIL-SPEC WS-1141.

The plasticizer containing a eutectic mixture of BDNPA/F has been commercially available and widely used in explosives and propellants. But it is well known that the thermal/chemical stability of an acetal group in BDNPA is lower than that of the formal group in BDNPF. A plasticizer which is an approximately 1:1 molar binary eutectic mixture of bis(2,2-dinitropropyl) formal and 2,2-dinitrobutyl 2,2-dinitropropyl formal avoids some of these shortcomings [426]. This is a two-component mixed formal, BDNPF and 2,2-dinitropropyl 2,2-dinitrobutyl formal (DNPBF), in which DNPBF was used as an inhibitor of crystallization in BDNPF. The two-component mixed formal is obtained by reacting a mixture of 2,2-dinitropropanol and 2,2-dinitrobutanol with formaldehyde, but it is also known that about 10% of bis(2,2-dinitropropyl) diformal is always lost as an unwanted by-product.

BDNPA/F mixture is an excellent plasticizer for polyurethanes, polyethylene glycols (PEG), and cellulose acetate butyrates (CAB). It has a low melting point (about 285 K = 12°C) and a low vapor pressure. A significant shortcoming of this mixture is the limited chemical and thermal stability of BDNPA. Thus, when heated separately at 423 K = 150°C in a vacuum for 48 h, BDNPF remains essentially unchanged whereas BDNPA decomposes to the extent of at least 30% with formation of new solid and liquid products which, in turn, undergo further decomposition. BDNPA is also more sensitive to acid hydrolysis than BDNPF. These undesirable properties of BDNPA are also exhibited by its eutectic mixture with BDNPF and adversely affect the utility of this mixed plasticizer.

Homologues to BDNPA/F containing butyl groups in place of propyl groups have similar properties and are also effective in lowering the melting point of BDNPF or BDNPA [427].

15.4.1 Production of BDNPA/F

Geminal dinitro energetic plasticizers are not easy to synthesize. In order to produce the mixture of BDNPA/F, the 2,2-dinitropropanol can be reacted with a mixture of formaldehyde and acetaldehyde, or the two compounds are produced separately, purified, and mixed later.

The oxidative nitration route and the chlorination-nitration route synthetic methods for production of bis(2,2-dinitropropyl)acetal/bis(2,2-dinitropropyl)formal (BDNPA/BDNPF, BDNPA/F) plasticizers were developed in the USA. The chlorination-nitration route is suitable for large-scale production.

Specifically, it has been found that boron trifluoride is an excellent catalyst in the production of bis(2,2-dinitropropyl) acetal, and that concentrated sulfuric acid (90–99% by weight) gives superior yields of formaldehyde, bis(2,2-dinitropropyl) formal [428].

A process for production of bis(2,2-dinitropropyl)formal (BDNPF) avoiding use of solvents reacts 2,2-dinitropropanol with a formaldehyde source in the presence of

a protic acid catalyst, such as H_2SO_4 , HCl , H_3PO_4 , or HBr at low temperatures between -30 and $+30^\circ\text{C}$ [429].

A similar process is used for production of bis(2,2-dinitropropyl)acetal (BDNPA) [425]. By replacing chlorinated solvents with MTBE (methyl-*tert*-butyl ether), the process has been made environmentally more friendly. The nitration can be carried out with inexpensive peroxy sulfate salts as the oxidant with a catalytic amount of potassium ferricyanide. The synthesis of BDNPA/F can be automated and run continuously to give a high output of product. The Thiokol Corporation has developed an environmentally friendly process which avoids the use of chlorinated solvents [430].

BDNPA/F was originally prepared by Kaplan and Schechter by oxidative nitration of nitroethane using silver nitrate as a catalyst. Due to process waste problems, and a loss of approximately 1% of silver, the process was considered economically and environmentally unattractive. Therefore, the Kaplan and Schechter route was eventually abandoned in the 1990s. The process was later modified by using selective chlorination of nitroethane to 1-chloronitroethane which improved the efficiency; however, the process was still considered environmentally unfriendly. The more recent manu-

facturing process for BDNPA/F used dinitropropanol (DNPOH) as a key intermediate [431]. DNPOH was prepared by selective chlorination of nitroethane to 1-chloro-1-nitroethane, followed by a ter Meer reaction of the later with nitrite ion in basic media to give the nitrate salt of 1,1-dinitroethane. This salt can then be easily converted to DNPOH. Through process improvement by minimizing the amount of buffering agent, the product per reactor volume was increased by a factor of eight. Similar improvements in the process for BDNPA were also achieved using acetaldehyde and an ion exchange resin.

BDNPA/F was commercially produced for many years using the ter Meer process. This chemistry was economical, efficient, and highly reproducible. Unfortunately, it utilized several environmentally unfavorable materials. Under US Army funding, the Thiokol Corporation developed and demonstrated a process which was environmentally more friendly [432]. The process was based on laboratory work done at Fluorochem on oxidative nitrations using aqueous, non-chlorine chemistry. Modifications to the original chemistry involved replacement of the chlorinated solvent with environmentally benign solvents in formation of the dinitropropanol (DNPOH) intermediate. The conversions of DNPOH to the acetal (A) and formal (F) were accomplished in non-solvent processes for the ether formation followed by a simple aqueous/methyl-*tert*-butyl ether-extractive work-up. In these reactions, no chlorinated solvents were used at any stage of the process. Yields and purity were demonstrated to be similar to those obtained by earlier processes. This process has been demonstrated in a pilot plant operated by the Thiokol Corporation and shown to produce material that meets all specification requirements as well as or better than the previous process but without multi-step purification. The process was scaled up to be used in larger pilot-scale production.

The thermal and chemical stabilities of BDNPA were worse than those of BDNPF, and several improved alternate compositions were proposed [433]. The energy content of DNBPF/BDNBF composite plasticizers is equal to that of the BDNPA/F mixture, but its chemical stability is better; therefore, it has some advantages and was predicted to eventually replace BDNPA/F. See also [434].

An energetic plasticizer which is a mixture of bis(2,2,2-trinitroethyl)formal, bis(2,2-dinitropropyl)formal, and 2,2-dinitropropyl 2,2,2-trinitroethyl formal was described in [435]. This patent described binary and ternary mixtures of BDNPF, bis(2,2,2-trinitroethyl)formal (TEFO), and 2,2-dinitropropyl-2,2,2-trinitroethylformal (TNEPF) as plasticizers for energetic propellant compositions. The general advantages of the binary and ternary mixtures of TNEPF, TEFO, and BDNPF are low volatility and good thermal stability (better than GTN or BTTN), coupled with a relatively high energy content [higher than BDNPA/F, diethylene glycol dinitrate (DEGDN), or trimethylolethane trinitrate (TMETN)]. These mixtures can be advantageously used in place of BDNPA/F, TMETN, or BTTN for many propellant applications. They are particularly suitable for plasticizing polymers like cellulose acetate butyrate (CAB), NC, polyethylene glycol (PEG), or polycaprolactone (PCP).

15.4.2 Physical Properties of BDNPA/F

BDNPA/F has good density ($\rho = 1.383\text{--}1.397\text{ g/cm}^3$) and viscosity and low toxicity properties and is compatible with many components of propellants and explosives [436]. Due to its good thermal stability, BDNPA/F can replace NG in formulations and reduce their impact sensitivity [437]. Due to the energy content and the excellent oxygen balance and heat of reaction values, BDNPA/F can replace inert plasticizers in formulations and improve the burning rate and specific impulse. It is widely used in double-base (DB) and CMDB propellants and explosive formulations such as PBX and Picatinny Arsenal Explosive (PAX). It is one of the most versatile energetic plasticizers for preparing insensitive energetic materials.

The heat of vaporization (ΔH_{vap}) and vapor pressure at 298 K (25°C) are $93.01 \pm 0.38\text{ kJ/mol}$ and $1.4532 \pm 0.40 / -0.27\text{ mPa}$ for BDNPA, and $84.77 \pm 0.88\text{ kJ/mol}$ and $2.20 \pm 1.87 / -1.07\text{ mPa}$ for BDNPF [438].

Molecular orbital calculations applied to a eutectic mixture of bis(2,2-dinitropropyl)formal and bis(2,2-dinitropropyl)acetal allowed predictions of thermodynamic and fluid properties [439].

15.4.3 Thermal Stability and Decomposition of BDNPA/F

Simultaneous thermogravimetric modulated beam mass spectrometry (STMBMS) and Fourier-transform ion cyclotron resonance (FTICR) instruments have been used to measure the mass spectra, measure vapor pressures, and evaluate the thermal decomposition mechanism of bis(2,2-dinitropropyl)acetal (BDNPA) and bis(2,2-dinitropropyl)formal (BDNPF) [438]. The FTICR mass spectra provided the identity of the ion fragments formed in the mass spectra of BDNPA, BDNPF, and their decomposition products, and provided a basis for predicting possible structures of the ion fragments. STMBMS data supported a nitro–nitrite ($\text{NO}_2 \rightarrow \text{ONO}$) rearrangement mechanism for both compounds. Upon rearrangement, both NO and NO_2 are cleaved from the structure, thus producing a ketone radical. The nitro–nitrite rearrangement begins to occur at appreciable rates between 433 and 435 K (160 and 180°C). Additional decomposition products included amines, imines, and amides, as well as CO_2 and H_2O at higher temperatures. The major difference between the decomposition of the two compounds is the slower reaction rate of BDNPF. It was postulated that the less sterically hindered carbon atom at the formal group of BDNPF subjects it to interactions with an intermediate, thus forming a complex and delaying its release.

In investigating complex reaction processes that control the behavior of heterogeneous energetic materials in munitions throughout their life cycle, the decomposition of BDNPA/F was studied by developing mathematical models of complex reaction processes [440].

The ease of hydrolysis of BDNPA/F limits its useful life in a moist environment, but also makes the disposal during demilitarization a little easier. The kinetics and mecha-

nism for the basic hydrolysis of BDNPA and BDNPF have been investigated [441]. Both BDNPA and BDNPF were found to react with slightly more than four mols of base to yield nitrite, 1,1-dinitroethane, acetate, and formiate anions. Second-order rate constants were obtained for both BDNPA and BDNPF for the expression

$$-d[\text{BDNPA}]/dt = k_1[\text{BDNPA}] = k_2[\text{B}^{(-)}][\text{BDNPA}]$$

where k_1 is the first order rate constant with excess base, $\text{B}^{(-)}$. BDNPA and BDNPF were found to react faster in dioxane/water than in water. The rates of disappearance of both BDNPA and BDNPF were very nearly equal to one half of the combined rates for the formation of nitrite and 1,1-dinitroethane anions. On the basis of relative k_2 values, BDNPA and BDNPF were found to react 40-times faster with aqueous base than triethylene glycol dinitrate (TEGDN), but 1000-times slower than RDX.

15.5 Other Nitroalkyl Formals and Acetals

Bis(dinitroalkyl)acetals and formals having the formula I

(R_1 , R_3 = independently straight or branched chain alkyl; R_2 = H, Me, Et, *n*-Pr, or isopropyl), particularly bis(2,2-dinitropropyl)acetal (BDNPA) and bis(2,2-dinitropropyl)formal (BDNPF), can be produced by oxidative nitration of compounds having the formula II

preferably via a sodium or other alkali metal, or alkaline earth metal, salt of II [442]. For example, condensation of 2-nitro-1-propanol with formaldehyde gave bis(2-nitropropyl)formal (BNPF), which produced bis(2,2-dinitropropyl)formal (BDNPF) by oxidative nitration with sodium nitrite.

The heat of formation of bis(2,2,2-trinitroethyl)formal, CAS RN [6263-74-7], was determined by combustion calorimetry, using a Pt-lined rotating-bomb calorimeter and was found to be $-403.3 \pm 2.68 \text{ kJ/mol} = -96.40 \pm 0.64 \text{ kcal/mol}$ [443].

An energetic plasticizer consists of bis(2,2-dinitropropyl)formal and a freezing point depressant that keeps BDNPF from crystallizing out, such as bis(2,2-dinitropropyl)diformal (BDNPDF) [444]. In cases where BDNPDF is used to prevent BDNPF from crystallizing out, BDNPF was not crystallized even though it was stored at 253 K (−20 °C) for more than 6 months, while its thermal and chemical properties were similar to those of conventional plasticizers. Also, by using BDNPDF, which had previously been considered as a unfavorable side product, as an inhibitor of crystallization, is no additional process required to remove BDNPDF.

A eutectic mixture consisting of bis(2,2-dinitropropyl)formal, 2,2-dinitropropyl-2,2-dinitrobutylformal, and bis(2,2-dinitrobutyl)formal also avoids the unwanted crystallization of BDNPF [427].

15.5.1 Fluoronitroalkyl Formals and Acetals

An energetic plasticizer, bis-2-fluoro-2,2-dinitroethoxymethylene,

which for brevity was given the acronym FEME, was prepared by condensation of fluorodinitroethanol with the appropriate alkyl ditriflates [445]. These plasticizers had been developed specifically for use with the dinitropropylvinyl ether polymer (DNPVEP). These plasticizers may also be used as replacements for FEFO or glycerin trinitrate which have availability and/or sensitivity problems. Preliminary evaluation of FEME indicated a high degree of both thermal and hydrolytic stability. DNPVEP plasticized with FEME showed excellent physical properties. Similar, less volatile plasticizers were developed that had more than one methylene group in the middle:

A variety of polynitroaliphatic acetals and ethers could be prepared under mild reaction conditions [446]. Purification was simple and no costly high-pressure or high-temperature laboratory techniques were necessary to produce a variety of polynitroaliphatic compounds not available via previously described synthetic methods. These energetic polynitroaliphatic acetals and ethers prepared from 2-fluoro-2,2-dinitroethanol could provide precursor compounds for eventual application as energetic binders or plasticizers in solid propellant and/or explosive formulations. Several activated alkenes and one alkyne were reacted with polynitroaliphatic alcohols directly to produce acetal and ether compounds. Difunctional polynitroalcohols reacted similarly with divinyl ether to produce low-molecular-weight acetal prepolymer compounds which were either vinyl or hydroxyl terminated. In one case, fluorodinitromethane was added to an alkene; however, the resultant product turned out to be unstable at room temperature and gradually decomposed.

The direct, one-step addition of 2-fluoro-2,2-dinitroethanol (FDNEOH) to certain unsaturated hydrocarbons formed 2-fluoro-2,2-dinitroethoxy acetal and ether compounds in high yield [447]. These non-aqueous mercury salt-catalyzed Markovnikov additions with FDNEOH were achieved under mild, neutral reaction conditions.

The fluorination of aqueous solutions of the salts of two formals, bis(2,2-dinitroethyl) formal (I) and bis(2,2,4,4-tetranitrobutyl) formal (II), with elemental fluorine resulted in the formation of fluorodinitroalkyl formals, bis(2-fluoro-2,2-dinitroethyl) formal, and bis(4-fluoro-2,2,4,4-tetranitrobutyl) [448]. Example (I) is shown:

The two selected salts represent in some way limiting compounds in a series of polynitro alcohol formals in that they exhibit a broad range of conditions for the aqueous fluorination of this class of compounds. The reaction for the fluorination of nitro compounds with elemental fluorine in water represents a system of two competing reactions: the reaction of fluorine with water, and the reaction of fluorine with the dissolved substance.

16 Fluoronitroalkanes

Many of the nitroalkanes discussed up to this point contained hydrogen on the alkyl group, making the compounds potential monopropellants but also increasing their sensitivity toward accidental explosions. Because some of the oxygen on the nitro groups is consumed to combust the hydrogen in the alkyl groups, these nitroalkane compounds are usually poor oxidizers. The oxygen balance of nitroalkanes can be improved by replacing some or all of the hydrogen in the alkyl group with fluorine. A wide variety of fluoronitroalkanes, fluoronitroethers, fluoronitroesters, and fluoronitroamines have been synthesized and evaluated as energetic plasticizers. Most of these have been patented but have never seen any practical applications. The energy content was often increased by adding difluoroamino or nitrate or azido groups to the molecule. Only a few randomly selected examples of these compounds are referenced in this book; a comprehensive summary would have exceeded the scope. Several fluoronitroalkanes have been evaluated as rocket propellants.

16.1 Fluorotrinitromethane

The simplest fluoronitroalkane is fluorotrinitromethane, fluoronitroform, $\text{FC}(\text{NO}_2)_3$, CAS RN [1840-42-2]. It can be prepared by fluorination of nitroform. Over-fluorination

can be avoided by continuously monitoring the concentration of remaining fluoroform by its UV absorption in a side stream that is returned to the reactor [449].

Fluorotrinitromethane can be synthesized by reacting tetranitromethane with an adduct of an alkali metal fluoride and a fluorinated or chlorofluorinated acetone in an aprotic dipolar solvent [450]. Chlorine or bromine may have to be added during the reaction so as to eliminate side reactions [451]. Physical properties of fluorotrinitromethane were summarized in [452].

Fluorotrinitromethane has been evaluated as a freezing point depressant for N_2O_4 . Physical properties were reported as follows [453]: its freezing point is $244.1\text{ K} = -29^\circ\text{C}$; the boiling point is $357.3\text{ K} = 84.2^\circ\text{C}$ at 760.1 mm Hg ; the standard enthalpy of formation of trinitrofluoromethane is $-217.5 \pm 2.0\text{ kJ/mol}$ ($-51.99 \pm 0.48\text{ kcal/mol}$). The density of fluorotrinitromethane for the range $293\text{--}338\text{ K}$ ($20\text{--}65^\circ\text{C}$) can be calculated from

$$\rho = 1.8459 - 0.002415t$$

where ρ is the density in g/cm^3 and t is the temperature in $^\circ\text{C}$. The vapor pressure for the range $273\text{--}357\text{ K}$ ($0\text{--}84^\circ\text{C}$) can be calculated from

$$\log P = 6.8187 - 1785.71/T$$

where P is the vapor pressure in mm Hg and T is the temperature in kelvin. The calculated heat of vaporization (Clausius–Clapeyron) is $\Delta H_{\text{vap}} = 34.2\text{ kJ/mol} = 8.171\text{ kcal/mol}$. The refractive index n_D^{25} is 1.3944.

The density reported by Zimmer et al. in 1966 was later corrected and shown to be 1.7954 g/cm^3 at 293 K (20°C) [454].

16.2 C₂ Fluoronitroalkanes

1-Fluoro-1,1-dinitroethane can be prepared by bubbling perchloryl fluoride into a suspension of potassium 1,1-dinitroethane in methanol/water at $313\text{ K} = 40^\circ\text{C}$, about 7 hours being required for complete replacement of the insoluble yellow crystals by white potassium chlorate [383]. After filtering off KClO_3 , dilution with water and extraction with ether, the ether phase was washed several times with water to remove most of the methanol, dried over calcium chloride, and the ether evaporated off *in vacuo*. Fractionation of the residue through a jacketed column packed with glass helices yielded 54% pure fluorodinitroethane, b.p. $313.6\text{--}314.6\text{ K}$ @ $2.6\text{ kPa} = 40.5\text{--}41.5^\circ\text{C}$ @ 20 mm Hg , n_D^{24} 1.3960.

16.3 Higher Fluoronitroalkanes

Fluoropolynitro organic formals like bis(2-fluoro-2,2-dinitroethyl)formal (FEFO, 2,2-dinitropropyl 2-fluoro-2,2-dinitroethyl formal) were evaluated as energetic plasticizers in propellant and explosive compositions and compared to BDNPF [413]. FEFO has a higher energy content but is volatile and toxic and has a relatively higher melting point. Furthermore, FEFO is unstable because it has a formal linkage which is hydrolytically unstable. BDNPF is comparatively low in energy and has a higher melting point, requiring the use of a melting point depressant at the expense of energy content. Mixtures of FEFO and BDNPF can be used to obtain a lower melting point and intermediate levels of energy and volatility.

In the series, $\text{CF}(\text{NO}_2)_2\text{—CH}_2\text{—O}(\text{—CH}_2\text{—O—})_n\text{—CH}_2\text{—CF}(\text{NO}_2)_2$, two oxymethylene homologues of FEFO ($n=1$) with $n=2$ and $n=3$ were prepared from 2-fluoro-2,2-dinitroethanol and formaldehyde in sulfuric acid [455]. Not unexpectedly, they were less thermally stable than FEFO. Vacuum thermal stability tests of the lowest member of this series, bis(2-fluoro-2,2-dinitroethyl) ether, $n=0$, made from bis(2-nitroethyl) ether by oxidative nitration and aqueous fluorination of the product, indicated that it possessed greater thermal stability than FEFO.

A homologue of FEFO, bis(2-fluoro-2,2-dinitroethoxy)-(1-fluoro-1,1-dinitro-2-propoxy) methane (M-FDNEOF) has been found to be useful as an energetic co-plasticizer for bis(2-fluoro-2,2-dinitroethyl) formal (FEFO) in PBX formulations [456]. M-FDNEOF is a low melting solid (m.p. 320–322 K = 47–49 °C) with a calculated liquid density at 298 K = 25 °C of 1.60 g/cm³. Its heat of formation was estimated to be –1314 kJ/mol = –314 kcal/mol. M-FDNEOF is almost equal to FEFO in energy content.

A general reaction of the transformation of the fluorodinitromethyl group into the fluoronitromethyl group by de-nitration upon treatment with Na₂SO₃ or KI in aqueous formaldehyde was found and a preparative method for synthesizing fluoronitroalcohols was developed on the basis of this reaction [457]. In this reaction, the compound loses one of its two nitro groups and a –CH₂OH group is added in its place. The fluorine remains attached.

The aim of the following work was to examine the possibility of applying an equation that correlates the frequency of the C–F valence vibration in IR spectra with the electronegativity of substituents in monofluoronitroalkanes of varied structure, and at the same time to study the influence of inter-molecular hydrogen bonding and the structure of the molecules on the vibration frequency of the C–F bond [458]. Compounds studied included fluoronitroform, fluorodinitromethane, 1-fluoro-1,1-dinitroethane, 1-fluoro-1-nitroethane, 1-fluoro-1,1-dinitropropane, 1-fluoro-2,2,2-trinitroethane, and 1-fluoro-3,3,3-trinitropropane. Fluorine takes part in the formation of inter-molecular hydrogen bonds in the fluoronitroalkanes because the frequency shifted with increasing dilution in a solvent.

A method was developed for the preparation of 1-fluoro-1-nitroalkanes and the principal physicochemical properties of eight members of a homologous series were described [459]. Two attempts have already been reported in the literature on the α -fluorination of primary mono-nitroalkanes with perchloryl fluoride and elemental fluorine. The first attempt proved to be completely unsuccessful, and a fluorine-containing nitroalkane could not be obtained.

Different classes of α -fluoropolynitrohydrocarbons, and specifically aliphatic (saturated and unsaturated) and aralkyl derivatives, were obtained by the action of perchloryl fluoride in various solvents on the alkali and ammonium salts of polynitrohydrocarbons [460]. Previously it had been shown that perchloryl fluoride (FCIO_3) was capable of fluorinating the salts of trinitromethane and *gem*-dinitroalkanes with the formation of the corresponding α -fluoropolynitroalkanes. The salts of different classes of polynitrohydrocarbons, and specifically the salts of polynitroalkanes, polynitroalkenes, and aralkyl polynitro compounds, and also the salts of halopolynitroalkanes were prepared in this way. The general equation for the reaction is

where $\text{R} = \text{NO}_2, \text{Cl}, \text{Br}, \text{H}, \text{alkyl}, \text{alkenyl}, \text{etc.}$, and M is the cation of an alkali metal. Table 27 gives a summary of properties of fluorodinitroalkanes prepared by this method.

Table 27: Properties of fluorodinitroalkanes.

Compound	Boiling point or boiling range (pressure)		Freezing point		Refractive index	Density
	K (kPa)	°C (mm Hg)	K	°C	n_D^{20}	g/cm^3
$\text{FC}(\text{NO}_2)_3$	356.6 (98.9)	83.5 (744)	228*	-45*	1.3950	1.5966
$\text{FCH}(\text{NO}_2)_2$	313 (3.2)	40 (24)	—	—	1.4060	1.6035
$\text{FC}(\text{NO}_2)_2\text{CH}_3$	403.6 (99.8)	130.5 (751)	235	-38	1.3992	1.4308
$\text{FC}(\text{NO}_2)_2\text{CH}_2\text{CH}_3$	323.1–323.6 (2.6)	50–50.5 (20)	—	—	1.4030	1.3339
$\text{FC}(\text{NO}_2)_2\text{CH}_2\text{CH}_2\text{CH}_3$	329.1–329.6 (1.9)	56–56.5 (14)	—	—	1.4090	1.2603

Data source: [460]

* This melting point does not agree with data from [453]

The enthalpy of formation of bis(dinitro) fluoropropane, $\text{C}_3\text{H}_5\text{N}_2\text{O}_4\text{F}_1$, with a molecular mass of 152.08 g/mol is $-530 \text{ cal/g} = -80.6 \text{ kcal/mol} = -337 \text{ kJ/mol}$ [97].

The reaction of 2-fluoro-2,2-dinitroethanol with dichlorine heptoxide gives 2-fluoro-2,2-dinitroethyl perchlorate, a very potent oxidizer [461]. Perchloryl fluoride reacted with 2-fluoro-2,2-dinitroethanol in methanol to give 2-fluoro-2,2-dinitroethyl methyl ether.

Thermal explosion times as a function of temperature have been measured for six dinitroalkanes and fluorodinitroalkanes at 1, 10, and 50 kbar [462]. For a constant thermal explosion time of 30 s, the thermal explosion temperatures were: 1,1-dinitroethane (at 1 kbar) 456 K = 183 °C and (at 10 kbar) 435 K = 162 °C; 1,1,1-fluorodinitroethane (at 1 kbar) 531 K = 258 °C and (at 10 kbar) 528 K = 255 °C; 1,1-dinitropropane (10 kbar) 435 K = 162 °C; 1,1,1-fluorodinitropropane (10 kbar) 530 K = 257 °C; 1,2-dinitropropane (1 kbar) 498 K = 225 °C, (10 kbar) 445 K = 172 °C, and (50 kbar) 416 K = 143 °C; and 2,2-dinitropropane (10 kbar) 530 K = 257 °C and (50 kbar) 571 K = 298 °C. The results for the dinitroalkanes showed that the presence of an α -hydrogen atom decreased the explosion temperature at constant pressure and increased the sensitivity to pressure. See also [463].

16.3.1 Compounds with Terminal Fluorodinitromethyl Groups

From steric and energetic theoretical considerations [464, 465] it was predicted that compounds containing the $(\text{O}_2\text{N})_2\text{FC}-$ grouping would constitute a class in which reduced sensitivity to impact and improved thermal stability could be achieved without excessive sacrifice of explosive power. A family of fluorodinitro high explosives and plasticizers was synthesized for which the prediction of reduced sensitivity and improved thermal stability with relatively little loss in explosive power appears to have been borne out [466]. Of particular interest were fluorodinitroethyl fluorodinitrobutyrate, bis-fluorodinitroethyl carbonate, and fluorodinitroethyl orthocarbonate. Alkyl nitrate esters with terminal fluorodinitromethyl groups have exceptional thermal stability and good energy content.

16.3.2 1,3-Bis(2'-Fluoro-2',2'-Dinitroethoxy)-2,2-Bis(Difluoroamino)Propane

There may be some overlap in the information provided in this book on difluoroamino compounds and nitro compounds. If one requires a complete evaluation of those mixed substituent energetic compounds, one will need to read both sections.

Another high-energy liquid which makes a good plasticizer is 1,3-bis(2'-fluoro-2',2'-dinitroethoxy)-2,2-bis(difluoroamino)propane, also known as $[\text{FC}(\text{NO}_2)_2\text{CH}_2\text{OCH}_2]_2\text{C}(\text{NF}_2)_2$, SYEP, CAS RN [7790-98-9].

Another energetic plasticizer and intermediate is 2,2-bis(difluoroamino)-5-fluoro-5,5-dinitro-1-pentanol, $(\text{O}_2\text{N})_2\text{FC}-\text{CH}_2-\text{CH}_2-\text{C}(\text{NF}_2)_2-\text{CH}_2-\text{OH}$, which can be synthesized by reacting 2,2-bis(difluoroamino)-5-fluoro-5,5-dinitro-1-pentyl trifluoroacetate with methanol [469]. It melts at 287 K (14 °C) and boils at 352–353 K (79–80 °C).

17 Nitroazidoalkanes (Azidonitroalkanes)

Compounds that contain both nitro groups and azido groups attached to a carbon skeleton are very energetic and can be used as energetic plasticizers. In trying to decide if these compounds should be listed here under “Nitroaliphatic Compounds” or in the organic “Azides and Azido Compounds”, it was decided that these compounds should be listed here under “Nitroaliphatic Compounds”, and not under “Azides and Azido Compounds.” This was done although the International Union of Pure and Applied Chemistry (IUPAC) conventions require us to form the name of nitro-azido-alkanes and nitro-azido-ethers by listing the number of nitro groups first and the number of azido groups last (not in alphabetical order). This is because in the IUPAC Decreasing Order of Precedence for the Major Functional Groups, *nitro* takes precedence over *azido* as a substituent on an alkyl group.

Similar compounds are formed by adding an azido group to the alkyl group in alkyl nitrates. These azidoalkyl nitrate compounds are discussed in chapter “Nitrate Esters” of *Encyclopedia of Oxidizers*.

An electrochemical method for the synthesis of geminal azidonitro compounds involved electro-oxidative coupling of azide anions with salts of nitro compounds and produced geminal azidonitroalkanes, azidonitrocycloalkanes, and diazidodinitrocycloalkanes in 45–92% yields [470]. Geminal azidonitroalkanes, azidonitrocycloalkanes, and diazidodinitrocycloalkanes are of considerable interest as compounds with a high energy capacity and promising synthons for construction of various polynitrogenous structures. However, only a few compounds of these types have been obtained and characterized to date: 1-azido-1-nitroethane, 1-azido-1-nitrobutane, 1-azido-1-nitrocyclohexane, 2-azido-2-nitropropane, 1,4-diazido-1,4-dinitrocyclohexane, and 2,5-diazido-2,5-dinitronorbornane. The best results were attained in oxidative coupling of azide anions with salts of nitro compounds with $\text{K}_3\text{Fe}(\text{CN})_6$ and $(\text{NH}_4)_2\text{S}_2\text{O}_8$ as the oxidants. A significant drawback of the methods is that a multiple molar excess of the oxidant and azide ions should be used which leads to the generation of a large amount of toxic waste. In contrast, the electro-oxidative coupling of azide with the anions of nitro compounds is a clean process.

α -Nitro-azides can be prepared by two routes involving intermediate radical anions and undergo substitution by an $\text{S}_{\text{RN}}1$ mechanism with azides, sulfonates, thiolates, and nitronates [471].

Oxidative azidation reactions of C-nitro-substituted saturated heterocyclic compounds, in particular the nitro derivatives of oxetane, azetidine, 1,3-dioxane, tetrahydro-1,3-oxazine, and hexahydropyrimidine, resulted in the formation of geminal nitro azides [472]. A recent book on liquid explosives contains a chapter on azido liquid explosives [473]. Azido fluorodinitro amines will be discussed in more detail in the section on substituted alkyl amines in *Encyclopedia of Liquid Fuels*, chapter "Aliphatic Amines" [474, 475].

Azidonitroalkane plasticizers have attracted attention due to their excellent performance as rocket propellant ingredients. In a search for new and promising azidonitroalkanes for plasticizers, a systematic theoretical investigation was performed using density functional theory and molecular dynamics methods [476]. In the first part, a series of azidonitroalkanes were designed and studied using the DFT method, showing high chemical and thermal stabilities. In the second part, an azidonitroalkane was taken as an example to explore the plasticizing effect of azidonitroalkanes on GAP.

17.1 C₂ Nitroazidoalkanes

1,1-Dinitro-1-azidoethane (1-azido-1,1-dinitroethane) can be prepared by reaction of 1,1,1-trinitroethane with lithium azide in a dipolar aprotic solvent (dimethylformamide or dimethylsulfoxide) [477]. This method gives a better yield than electrolysis of a slightly alkaline solution of a primary geminal dinitroalkane and sodium azide on a smooth platinum electrode [478].

1-Azido-1,1-dinitroethane may be too sensitive to be used as a monopropellant by itself, so it was proposed to desensitize it by addition of 10 to 30% methanol, 2-azidoethanol, 1,3-diazidopropanol, or 1,4-diazido-1,1-dinitrobutane and use those mixtures as monopropellants [479].

17.2 C₃ Nitroazidoalkanes

2-Azido-2-nitropropane and 1-azido-1-nitrocyclohexane can be prepared by reactions involving intermediate radical anions (S_RN_1 and oxidative addition) [480]. S_RN_1 reactions between α -nitroazides and azide, benzenesulfinate, and p-chlorobenzenethiolate proceeded with loss of nitrite. The S_RN_1 reaction between 1-azido-1-nitrocyclohexane and the anion of 2-nitropropane proceeded with loss of azide.

Another azidonitro compound which is of interest as an energetic plasticizer is 2,2-dinitro-1,3-diazidopropane [481].

17.3 C₄ Nitroazidoalkanes

The reaction of salts of 1-*aci*-nitroethane and 1-*aci*-nitrobutane with sodium azide and ammonium peroxodisulfate in a methylene chloride/water two-phase system resulted in 1-azido-1-nitroethane and 1-azido-1-nitrobutane, respectively [482].

4,4-Dinitro-1-butanol can be prepared by reacting trinitromethane with acrolein, reducing the resulting trinitroaldehyde to provide the corresponding alcohol, and reducing the alcohol [483]. 4-Azido-4,4-dinitro-1-butyl acetate can be prepared by reacting 4,4-dinitro-1-butanol with acetyl chloride to yield the corresponding acetate and reacting the acetate with an alkali metal azide in an electrolysis cell.

17.4 C₅ Nitroazidoalkanes

Another example of an azidonitroalkane is 1,2-diazido-3-fluoro-dinitroethoxypropane, C₅H₇FN₈O₅, (O₂N)₂CF—CH₂—O—CH₂—CH(N₃)—CH₂N₃, DAFP, which is a yellow liquid with a density of 1.44 g/cm³ and a refractive index of $n_D^{25} = 1.4832$. The enthalpy of formation is +368 kJ/mol (+88 kcal/mol). It froze to a glass at 243 K (−30 °C) and in the DSC had an onset of exotherm at 458 K (185 °C) [484].

17.5 C₆ Nitroazidoalkanes

Aliphatic ethers containing both fluorodinitro and azido moieties are 2-fluoro-2,2-dinitroethyl 2-azidoethyl ether, (NO₂)₂FC—CH₂—O—CH₂—CH₂—N₃ [485]. 1,3-Diazido-2-propyl 2'-fluoro-2',2'-dinitroethyl formal, (NO₂)₂FC—CH₂—O—CH₂—O—CH(CH₂—N₃)₂ is a light-yellow liquid, $n_D^{25} = 1.4798$. Azidomethyl 2-fluoro-2,2-dinitroethyl ether is a light-yellow liquid, $n_D^{27} = 1.4478$, $d^{25} = 1.4707$ g/cm³.

17.6 C₇ – C₁₀ Nitroazidoalkanes

Tri(azido-acetoxymethyl)nitromethane, (N₃CH₂CO—O—CH₂)₃CNO₂, was synthesized with a total yield of 83% using tris(hydroxymethyl)nitromethane as raw material, via a two-step reaction of esterification and azidation [486]. Its molecular structure was confirmed by IR, NMR, and elemental analysis. The density was 1.45 g/cm³, decomposition temperature was 509 K (236 °C), glass transition temperature was 247 K (−26 °C), drop-weight impact sensitivity was $H_{50} = 44.7$ cm (2 kg).

18 Other Polynitroalkyl Derivatives

The structures and properties of the isomers of the first three members of the series $C_n(CNO_3)_{2n+2}$ ($n=0,1,2$) compound featuring NO_3 groups bound to a carbon through their three oxygen atoms were examined by computational chemistry [487]. The first member of the series, $(CNO_3)_2$, has six possible isomers, di(nitrato-O)acetylene, *cis*- and *trans*-di(nitrato-O,O-)ethylene, di(nitrato-O,O,O)ethane or bis(nitratoxycarbon), di(nitroso)oxalate, and the mixed isomer nitroso(nitrato-O,O,O)acetate. The most stable of these isomers is di(nitroso)oxalate, followed by nitroso(nitrato-O,O,O)acetate, and bis(nitratoxycarbon). Of the two higher members of the series investigated, $C_n(CNO_3)_{2n+2}$ ($n=1,2$), each has two isomers: the nitritocarbonyl-substituted systems analogous to di(nitroso)oxalate and the nitratoxycarbon-substituted systems (neglecting mixed isomers containing both nitritocarbonyl and nitratoxycarbon moieties). The nitritocarbonyl derivatives were found to be significantly more thermodynamically stable than the nitratoxycarbon derivatives.

The vibrational stability of the theoretical molecule tetrakis(nitratoxycarbon)-methane, designated CLL-1,

was predicted by *ab initio* electronic structure calculations [488]. The gas-phase enthalpy of formation, predicted to be +1029.3 kJ/mol, and the estimated density of 1.87 g/cm³ were used to predict the explosive performance properties using the equilibrium thermochemical code CHEETAH. The predicted detonation velocity (8.61 km/s) and pressure (33.1 GPa) were similar to those of RDX, but with a significantly higher detonation temperature (6740 K). The synthetic chemists still have to follow the act of the theoretical chemists to make this molecule a reality. If they succeed, it would be an organic oxidizer with good oxygen content and high performance potential.

Tetranitroacetimidic acid, TNAA, $C_2H_1N_5O_9$, has been synthesized by way of cationic FOX-7 and fully characterized [489, 490]. It contains 60.2 mass-% oxygen. The properties of TNAA were found to be encouraging, with a calculated specific impulse exceeding that of AP, indicating its potential as a replacement for AP. TNAA can be synthesized easily in a one-step process by nitration of FOX-7 at room temperature in high yield (93%):

Molecules with the gross formula $C_1N_2O_3$ should be good oxidizers but have not been found yet. They exist only on paper or the computer screen. Structures and energies of $C_1N_2O_3$ isomers have been investigated theoretically by *ab initio* calculations in search of new high-energy molecules [491]. The most energetically favorable isomer, five-membered cyclic nitrous carbonate, had only a 67 kJ/mol (16 kcal/mol) dissociation barrier toward decomposition into CO_2 and N_2O . Nitroisocyanate, O_2N-NCO , was 121 kJ/mol (29 kcal/mol) higher in energy than nitrous carbonate and has a 46 kJ/mol (11 kcal/mol) barrier in the exothermic decomposition into CO_2 and N_2O , which involves formation of an intermediate four-membered cyclic form. Nitrofulminate has a higher C–N bond dissociation energy and is expected to be a more stable molecule than nitrosofulminate

Nitrofulminate was suggested as a potential energetic oxidizer. Another CN_2O_3 isomer, dinitrosocarbonyl, $OC(NO)_2$, has a low stability toward decomposition into CO and NO radicals.

Nitroaromatic Compounds

Coverage of nitro compounds had to be spread out over four chapters because a single chapter on the topic would have been very large and would have made it more difficult for readers to find information on a specific compound. In addition, arranging 30 chapters among 5 subvolumes in such a way that each subvolume was about the same size represented a formidable challenge. A book with smaller chapters made our task easier.

The other chapters in the group of nitro compounds are entitled “Nitro Compounds,” “Nitroaliphatic Compounds,” and “Nitromethanes.”

1 Nitroaromatic Compounds (Nitroarenes)

Nitroaromatic compounds, aromatic C-nitro compounds, also called nitroarenes, are nitro compounds where the nitro group(s) is (are) attached to an aromatic ring, typically a benzene ring. Because the benzene ring is more stable than some aliphatic chains with similar chemical compositions, nitroaromatic compounds are thermally more stable and in several instances more energetic than nitroaliphatic compounds. In spite of this, few nitroaromatic compounds are used in rocket propellants, and they may be used, if at all, as energetic additives in solid propellants. The main applications of nitroaromatic compounds are in explosives, not in rocket propellants.

The current chapter on nitroarenes is by far not as detailed as the earlier chapter on nitroalkanes. This is partially because there are sufficient other sources of information on this class of chemicals. A few of those are listed here as examples. The summary paper by Sikder and Sikder [1] contains numerous examples of nitroaromatic thermally stable explosives, such as hexanitrostilbene (HNS), 1,3,7,9-tetranitro-6H-benzotriazole[2,1-a]benzotriazole-5-onium inner salt (Z-TACOT), dipicramide (DIPAM), 2,2',2'',4,4',4'',6,6',6''-nonanitro-1,1':3',1''-terphenyl (NONA), 2,6-bis(picrylamino)-3,5-dinitropyridine (PYX), styphnic acid, picryl-substituted heterocyclic compounds, and others.

An excellent summary of the chemistry of nitroaromatic compounds with 305 references is Chapter 4 in the book by Agrawal and Hodgson 2007 [2]. It lists a wide array of methods for preparing nitroaromatic compounds, which are the mainstay of industrial and military explosives production, including 2,4,6-trinitrotoluene (TNT), 1,3,5-triamino-2,4,6-trinitrobenzene (TATB), HNS, picric acid, and many others.

1.1 Preparation of Nitroaromatic Compounds

The methods of preparation and a comparison of physical properties presented in the following sections apply to all nitroaromatic compounds as a group. Methods for specific nitroaromatic compounds will be discussed further down, one at a time.

Nucleophilic aromatic substitution is the main route to aromatic nitro compounds. The nitrating agent is mixed acid of nitric acid and sulfuric acid.

1.2 Physical Properties of Nitroaromatic Compounds

1.2.1 Melting Points of Nitroaromatic Compounds

Crystalline compounds melt when the thermal energy exceeds the intermolecular crystal bond strength. This process can be modeled by computer programs based on group additivity methods and gives fairly accurate predictions for nitroaromatic compounds [3–6]. Melting points depend on the number of hydrogen and nitrogen atoms as well as the contribution of some specific functional groups and the existence of ortho or para isomers in disubstituted benzene derivatives. Predicted melting points had an average deviation of 5%.

1.2.2 Densities of Nitroaromatic Compounds

Because nitroaromatic compounds are usually well crystallized and the densities have been measured accurately, these chemicals have often been used as model compounds to test the accuracy of predictive methods for the densities of energetic compounds. Different methods, such as group additivity methods and quantum mechanical approaches, can be used to estimate the density of many energetic organic compounds, in particular nitroaromatics. Since the reliable prediction of the density of energetic compounds is important for estimating their explosive performance, different approaches have been developed to predict the densities of energetic compounds. An improved method for the prediction of the density of energetic compounds using their molecular structure considered the fact that the presence of specific polar groups and molecular moieties may enhance or reduce the density of molecular packing [4, 7–9].

1.2.3 Thermodynamic Properties of Nitroaromatic Compounds

Similar density functional theory and *ab initio* methods are available to predict the thermodynamic properties of nitroaromatic compounds from their molecular structure.

1.2.3.1 Enthalpy of Formation of Nitroaromatic Compounds

The heats of formation of various aromatic nitro compounds were calculated with semi-empirical molecular orbital theory and molecular mechanics methods [10]. The enthalpies of formation ΔH_f° of energetic materials were predicted with sufficient accuracy to use ΔH_f° for energy hazard predictions. In the case of aromatic polynitro compounds, both methods may be able to calculate accurate ΔH_f° .

The heats of formation of nitrobenzenes and nitrotoluenes were calculated by quantum mechanical methods [11]. The accuracy of correlation for heats of formation between the theoretical calculations and experimental results was evaluated by a weighted least-squares multi-variable method. Based on these correlations, the heat of formation of some aromatic nitro compounds can be predicted accurately compared to the weighted least-squares multi-variable fitting to theoretical gas-phase and experimental crystal heats of formation for nitrobenzenes and nitrotoluenes. From these numbers, the heat of sublimation can be predicted theoretically. See also [12].

The ideal gas (**not** condensed phase!) thermodynamic properties of 29 nitro and nitrate compounds, high explosives such as TNT, 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX), 1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane (HMX), and pentaerythritol tetranitrate (PETN), were predicted from spectroscopic data and compared to calorimetric results reported in the literature [13, 14]. The fundamental vibrations, the bond lengths, and the moments of inertia of all molecules were calculated using semi-empirical methods. The resulting thermodynamic properties were represented in polynomial form, ready for use in rocket propulsion I_{sp} calculations. The format used was the old NASA Chemical Equilibrium Compositions (CEC) polynomial format and consisting of two sets of polynomial coefficients for each species. The first set of seven coefficients represented the properties above 1000 K, and the second from 200 to 1000 K. Both polynomials gave the same values at 1000 K for the properties. The results are summarized in Table 1.

Table 1: Ideal gas thermodynamic properties of nitro compounds.

Gaseous (vapor) compound name	Formula	ΔH_f^{298} kJ/mol	S^{298} JK ⁻¹ mol ⁻¹	C_p^{300} JK ⁻¹ mol ⁻¹
RDX hexogen	C ₃ H ₆ N ₆ O ₆	+192.00	482.44	231.26
HMX octogen	C ₄ H ₈ (N—NO ₂) ₄	+187.86	568.83	276.66
Nitrobenzene	C ₆ H ₅ NO ₂	+68.53	348.80	121.06
<i>n</i> -Nitrohexane	C ₆ H ₁₃ NO ₂	-185.35		
1,3,5-Trinitrobenzene	C ₆ H ₃ (NO ₂) ₃	+62.34	485.34	206.45
2,4,6-Trinitrotoluene	C ₇ H ₆ (NO ₂) ₃	+24.10	501.32	215.23

Data source: [14]

One model assumed that the heat of formation of a nitroaromatic compound of composition $C_aH_bN_cO_d$ could be expressed as a correlation that depends on elemental composition and various structural and special functional group contributions. Condensed-phase heats of formation predicted using this method had a root mean square (RMS) deviation of 5.9 kcal/mol for 19 well-known organic nitroaromatic compounds [15–18].

Gas-phase enthalpies of formation of nitroarenes TNT and TATB were calculated using the G2, G3, G4, and correlation consistent composite approach (ccCA-PS3) quantum composite methods [19]. G3 and G4 calculations are typically close to one another, with a larger difference found between these methods and ccCA-PS3. Although there is significant uncertainty in experimental values, the mean absolute deviation between the average experimental value and calculations were 12, 6, 7, and 3 kcal/mol for G2, G3, G4, and ccCA-PS3, respectively.

1.2.3.2 Heat of Combustion of Nitroaromatic Compounds

Methods similar to those for the prediction of enthalpy of formation can also be used to predict the heat of combustion of nitroarenes and other nitro compounds [20].

1.2.3.3 Enthalpy of Fusion of Nitroaromatic Compounds

The heats of fusion of nitroaromatic carbocyclic energetic compounds can be predicted using some structural parameters, elemental composition, and the contribution of some specific polar functional groups [21, 22]. Predicted heats of fusion for 41 nitroaromatic carbocyclic compounds were compared with experimental data. Calculated heats of fusion had an RMS deviation of 3 kJ/mol for these energetic compounds. A similar method can be used to predict the enthalpy of sublimation of nitroaromatic compounds [23].

1.3 Chemical Properties of Polynitroarenes

1.3.1 Thermal Stability and Thermolysis of Polynitroarenes

The activation energies of 20 polynitroarenes determined by differential scanning calorimetry (DSC) were compared to the kinetic data of a gas evolution manometric method and detonation properties [24]. There was no clear correlation between these properties.

The values of activation energies E_p from differential thermal analysis (DTA) measurements for the low-temperature intervals at the beginning of thermal decomposition T_d of nitroaromatic compounds corresponded to the non-autocatalyzed start of thermolysis [25]. This was documented by the existence of relationships between the values of E_p/T_d ratios and the characteristics of molecular structure, namely, the moments of inertia of alkyl groups in *N*-alkyl-2,4,6-trinitroanilines. There also exist

relationships between the values of E_p/T_d ratios and the values of Arrhenius parameters resulting from a gas evolution manometric method applied to the thermolysis of polynitroarenes.

Seventy-three polynitro compounds were subjected to thermal decomposition measurements using a manometric method or DSC [26]. From the kinetic data of the initial stage of the decomposition, corresponding values were calculated of the natural logarithm of equilibrium constants of the activated complex ($\ln K$). A relationship was found between the values $\ln K$ and $\ln D$, where D was the detonation velocity at maximum theoretical density of the compounds. Taking into account the relationships between thermochemical kinetic characteristics from DTA and detonation characteristics of polynitroaromatic compounds, it was concluded that the initial steps of thermolysis and initial detonation reactions of organic polynitro compounds are identical.

The activation energy or the Arrhenius parameter E_a of thermolysis in the condensed state for different polynitroarenes can be expressed as a function of optimized elemental composition as well as the contribution by specific molecular structural parameters [27]. The method can predict E_a of thermolysis and has an RMS and average deviations of 13.79 and 11.94 kJ/mol, respectively, for 20 typical polynitroarenes with different molecular structures.

1.4 Safety Properties of Polynitroarenes

Although polynitroarenes are used mainly as explosives and not as rocket propellants, it is interesting to follow relationships between molecular structure and sensitivity to accidental explosions. Similar relationships may apply to other energetic materials that are used as rocket propellants. The sensitivity of polynitroarenes and nitramines to mechanical impact and electrostatic discharge can be correlated to their molecular structure.

1.4.1 Impact Sensitivities of Polynitroarenes

The impact sensitivities of organic high explosives are primarily functions of the rates of the thermal decomposition processes taking place in the narrow temperature spikes generated under the impact hammer. For classes of explosives with similar decomposition mechanisms, there appear to be statistically significant linear relationships (sensitivity/composition trends) between logarithmic 50% impact heights and oxygen balance. It was shown that polynitroaromatic explosives containing a C—H linkage in the α -position to the aromatic ring are more sensitive as a class than explosives lacking such a linkage [28]. The products of thermal decomposition of TNT indicated a preferred site of inter- and intramolecular oxidative attack to be at the α C—H linkage.

The impact reactivity of 22 polynitroarenes was expressed as the drop energy, E_{drop} , required for 50% initiation probability. Relationships have been found between the E_{drop} values and heats of fusion, on the one hand, and ^{13}C NMR chemical shifts of carbon atoms in reaction centers, on the other [3].

In a similar study, published data of impact sensitivity of 33 polynitro compounds were expressed as the drop energy required for 50% initiation probability, and a logarithmic relationship was found between the E_{drop} values and heats of fusion of these compounds [29]. An analogous application of heats of sublimation has not given convincing results.

Simple correlations for the prediction of the impact sensitivity of $\text{C}_a\text{H}_b\text{N}_c\text{O}_d$ explosives using molecular weight and structure information were applied to test different polynitroaromatics, benzofuroxans, and nitramines, and the results were compared with experimental data and some models of complex quantum mechanics computation [30, 31]. The predicted impact sensitivities of 46 explosives had a RMS of deviation from experiment of 24 cm, which showed good agreement with respect to measured values compared to five different quantum mechanical models. The method can also be applied to polynitroheteroarenes [32]. Besides for polynitroarenes, similar relationships were established for nitropyridines, nitroimidazoles, nitropyrazoles, nitrofurazanes, nitrotriazoles, nitropyrimidines, benzofuroxans, nitramines, and nitroaliphatics containing other functional groups and alkyl nitrate energetic compounds [33].

1.4.2 Impact and Friction Sensitivities of Polynitroarenes

The impact and friction sensitivities of polynitroarenes are listed in Table 2. For additional data on impact sensitivity of polynitroaromatics see [34, 35].

Table 2: Impact and friction sensitivities of polynitroarenes.

Compound name	Impact sensitivity	Friction sensitivity, pistil load	
	N m	N	kg _f
Picric acid	7.4	no reaction at 353	no reaction at 36
Dinitrotoluene	no reaction at up to 50	no reaction at up to 353	no reaction at up to 36
Dinitrobenzene	39	no reaction at up to 353	no reaction at up to 36
1,3,5-Trinitrobenzene	7.4	no reaction at up to 353	no reaction at up to 36
Styphnic acid	7.4	no reaction at up to 353	no reaction at up to 36
2,4,6-Trinitrotoluene	15	no reaction at up to 353	no reaction at up to 36

Data source: Meyer, Koehler, and Homburg, 6th Ed. (2007); in the following abbreviated as MKH [36]

1.4.3 Electrostatic Discharge Sensitivities of Polynitroarenes

A simple correlation was introduced for predicting the electric spark sensitivity of nitroaromatic compounds. This approach was based on the number of carbons and hydrogens as well as the ratio of hydrogens to oxygens and the presence of certain groups, i.e., alkyl or alkoxy groups, attached to an aromatic ring [37]. The model was optimized using a set of 17 polynitroaromatic explosives as model set and then applied to 14 explosives from a variety of chemical families in order to assess the predictive capability of this method. Predicted results were reasonably close to the measured values for both model and test sets.

1.4.4 Explosive Performance of Polynitroarenes

A method proposed for quickly estimating heats of detonation of aromatic energetic compounds does not use any experimental or computed data of energetic materials. The methodology assumes that the heat of detonation of an energetic CHNO compound can be obtained from the number of nitrogens, ratios of oxygen to carbon and hydrogen to oxygen, and the contribution of some specific functional groups [38]. Predicted heats of detonation of pure energetic compounds with the product H_2O in the liquid state for 31 aromatic energetic compounds had an RMS of deviation of 0.32 kJ/g from experiment.

1.4.4.1 Detonation Pressure of Polynitroarenes

The Trauzl lead block indentations of typical nitroarenes are summarized in Table 3.

Table 3: Trauzl lead block indentations of polynitroarenes.

Compound	Lead block indentation, $\text{cm}^3/10 \text{ g}$
TATB	175
2,4-Dinitrotoluene	240
<i>m</i> -Dinitrobenzene	242
2,4,6-Trinitrotoluene	300
Picric acid	315
1,3,5-Trinitrobenzene	325
Tetryl	410

Data source: [36]

1.4.4.2 Detonation Velocity of Polynitroarenes

The confined detonation velocities of typical nitroarenes are summarized in Table 4.

Table 4: Detonation velocities of polynitroarenes.

Compound	Detonation velocity, m/s	Loading density, g/cm ³
2,4-Dinitrotoluene	5200	1.5
<i>m</i> -Dinitrobenzene	6100	1.47
2,4,6-Trinitrotoluene	6900	1.60
1,3,5-Trinitrobenzene	7300	1.71
TATB	7350	1.80
Picric acid	7350	1.7
Tetryl	7570	1.71

Data source: [36]

2 Nitrobenzenes

2.1 Nitrobenzene

Nitrobenzene, also known as mononitrobenzene, C₆H₅NO₂, CAS RN [98-95-3] is a light yellow liquid with a distinguishing odor of bitter almonds. Nitrobenzene does not contain sufficient energy to be used as a rocket propellant. It has been used as a fuel or solvent or desensitizer for other nitro compounds and alkyl nitrates and is an intermediate in the synthesis of many other aromatic compounds. The physical properties of nitrobenzene are summarized in Table 5.

Table 5: Physical properties of nitrobenzene.

Property	SI units	Other units	References
Molecular mass	123.1094		
Freezing point	278.9 ± 0.2 K	+5.8 °C	[39]

2.2 Dinitrobenzenes

There are three stereoisomeric dinitrobenzenes, *o*-, *m*-, and *p*-dinitrobenzene, $C_6H_4(NO_2)_2$, $C_6H_4N_2O_4$. They are more energetic than nitrobenzene but have not been used as rocket propellants. The oxygen balance is -95.2% and the nitrogen content is 16.67% N. The most commonly used dinitrobenzene is the *meta* isomer, *m*-dinitrobenzene, 1,3-dinitrobenzene, CAS RN [99-65-0]. It exists in the form of pale yellow needles at room temperature. Dinitrobenzene is sparingly soluble in water. It is prepared by direct nitration of benzene or nitrobenzene and is an insensitive explosive. For the purposes of official transport regulations, the sensitivity and reactivity of dinitrobenzene are just on the limit between high-explosive and the non-dangerous zone. Dinitrobenzenes are toxic and produce cyanosis. The maximum permissible concentration of *m*-dinitrobenzene in workplace air is 1 mg/m³. The compound is of little interest as an explosive, but mixtures of *m*-dinitrobenzene and nitric acid have been used as explosives. The physical properties of *m*-dinitrobenzene are listed in Table 6.

Table 6: Physical properties of *m*-dinitrobenzene.

Property	SI units		Other units	References
Molecular mass	168.1070 g/mol	5.9486 mols/kg		
Melting point	362.7 K		89.6 °C = 193.3 °F	[36]
Density	1.575 kg/dm ³		1.575 g/cm ³	[36]
Enthalpy of formation	-27.2 kJ/mol	-161.8 kJ/kg	-38.7 kcal/kg	[36]
Heat of combustion	2907 kJ/mol	17293 kJ/kg	694.7 kcal/mol	[41]

In the Trauzl lead block test, the cavity enlargement was 242 cm³/10 g. The detonation velocity of steel-wall-confined samples was 6100 m/s = 20 000 ft/s at $\rho = 1.47$ g/cm³. When heated, dinitrobenzene samples evaporated at 564 K = 291 °C = 556 °F but there was no deflagration. The drop weight impact sensitivity was 39 Nm and the friction sensitivity test showed no reaction up to the maximum load of 353 N (in the Bundesanstalt für Materialforschung und -prüfung (BAM) apparatus).

2.3 Trinitrobenzenes

There are three trinitrobenzene isomers, depending on the distribution of the three nitro groups on the benzene ring in symmetrical, asymmetrical, or vicinal positions. The most frequently used symmetrical 1,3,5-trinitrobenzene, also known as $C_6H_3(NO_2)_3$,

$C_6H_3N_3O_6$, TNB, CAS RN [99-35-4] contains nitro groups in the 1, 3, and 5 positions of the benzene ring:

1,3,5-TNB can be synthesized by converting phloroglucinol into its trioxime by reaction with aqueous hydroxylamine followed by oxidation of the trioxime product with 90% nitric acid [42].

2.3.1 Physical and Chemical Properties of Trinitrobenzenes

1,3,5-Trinitrobenzene forms greenish-yellow crystals that melt at 396.3 K (123.2°C = 253.7°F) [43]. In spite of the fact that TNB explosive yield and detonation velocity are higher than those of TNT, TNB has not found practical application as an explosive because it is more difficult to prepare than TNT. For the same reason, it will not find applications as a rocket propellant ingredient. In the solid state, TNB exists in two phases. The physical properties of TNBs are listed in Table 7.

Table 7: Physical properties of trinitrobenzenes.

2.3.2 Amino-trinitrobenzenes

The introduction of amino groups into a benzene ring that already has several nitro groups is one of the simplest approaches to enhancing the thermal stability of explosives. This is evident from a comparison of monoamino-2,4,6-trinitrobenzene (MATB), 1,3-diamino-2,4,6-trinitrobenzene (DATB), and 1,3,5-triamino-2,4,6-trinitrobenzene (TATB), where the order of increasing thermal stability is MATB < DATB < TATB [45].

2.3.2.1 1,3,5-Triamino-2,4,6-trinitrobenzene

1,3,5-Triamino-2,4,6-trinitrobenzene, also known as 1,3,5-benzenetriamine 2,4,6-trinitro-; *sym*-triaminotrinitrobenzene, $C_6(NH_2)_3(NO_2)_3$, $C_6H_6N_6O_6$, TATB, CAS RN [3058-38-6], has excellent thermal stability all the way up to the range 533–563 K (260–290 °C). TATB is an explosive with unusual insensitivity and heat resistance, and at the same time respectable performance, which makes it a prime-usage, thermally stable, and safe explosive [46]. 1,3,5-Triamino-2,4,6-trinitrobenzene is an explosive with exceptional thermal stability. There is evidence of strong intermolecular and intramolecular hydrogen bonding in TATB. Its thermal stability is the result of a sandwiched crystal structure in which both hydrogen bonding and π - π -interactions determine the arrangement of molecules in the crystal.

There is also the trinitrated diaminobenzene, diaminotrinitrobenzene, DATB, with a CAS RN of [1630-08-6].

There are no known uses of TATB as a rocket propellant. It resists heat up to 573 K (300 °C = 570 °F) and is relatively insensitive to friction and impact, but the critical diameter is large. TATB can be obtained by nitration of trichlorobenzene and conversion of the trinitrotrichlorobenzene to TATB. The unique structural features of the TATB molecule are as follows: (1) extremely long C—C bonds in the benzene ring, (2) very short C—N (amino) bonds, and (3) six furcated hydrogen bonds:

The net result is that TATB lacks an observable melting point and has a low solubility in all common solvents except concentrated H_2SO_4 .

TATB is not used as a rocket propellant, but its unique properties may lead propellant chemists to more energetic and thermally more stable propellant ingredients. The physical properties of TATB are listed in Table 8. The published data for the enthalpy of formation of TATB vary over a wide range.

Table 8: Physical properties of triaminotrinitrobenzene.

Property	SI units		Other units	References
Molecular mass	258.1484 g/mol	3.8737 mol/kg	3.8737 mol/kg	
Melting point	decomposes before melting			
Density	1.938 g/cm ³			[36]

Enthalpy of formation	-154 kJ/mol	-596 kJ/kg	-36.91 kcal/mol = -143 cal/g	[48, 49]
Enthalpy of formation	-139.7 kJ/mol	-541.3 kJ/kg	-33.40 kcal/mol	[36]
Heat of combustion	3079 ± 2 kJ/mol	11927 ± 8 kJ/kg	735.9 ± 0.5 kcal/mol	[47]

In the lead block test the enlargement of the cavity was 175 cm³/10 g. The detonation velocity in steel confinement was 7350 m/s at $\rho = 1.80$ g/cm³. The deflagration point was 657 K = 384 °C, which is one of the highest known for any high explosive. The impact sensitivity was 50 Nm, and the friction sensitivity test showed no reaction at the maximum pistil load of 353 N (BAM test apparatus).

Table 9 lists properties of TATB in comparison to those of other common explosives.

2.4 Hexanitrobenzene

Hexanitrobenzene is one of the compounds that contain only a carbon skeleton and nitro groups. These compounds are called nitrocarbons. Other compounds with similar structures are tetranitromethane (TNM), hexanitroethane, octanitrocubane, or decanitrobiphenyl. The density of hexanitrobenzene is 1.988 g/cm³. There is even a book devoted to these types of chemicals [51].

2.5 Decanitrobiphenyl

Decanitrobiphenyl is one of the compounds that contain only a carbon skeleton and nitro groups. The synthesis starts with *p*-chlorobenzoic acid over seven steps [52]. These compounds are called nitrocarbons. Other compounds with similar CNO compositions without any hydrogen are TNM, hexanitroethane, hexanitrobenzene, or octanitrocubane.

Table 9: Properties of TATB in comparison to those of other explosives.

Compound	Compound name	Gross formula	T _{dec} °C	ρ g/cm ³	ΔH _f kJ/mol	OB %	IS J	P _{CJ} GPa	V _{Det} m/s	FS N

3 Nitrotoluenes

Mononitrotoluene is a pale yellow liquid with empirical formula $C_7H_7O_2N$. There are three isomers, of which only the *ortho* and *para*-isomers can yield pure 2,4,6-trinitrotoluene on further nitration. Mononitration of toluene yields mostly the *ortho* compound, as well as 4% of the *meta*- and about 33% of the *para*- compound. Nitrotoluene is of importance as an intermediate or precursor for in the manufacture of dinitrotoluene (DNT) and TNT.

3.1 2,4-Dinitrotoluene

There are four dinitrotoluenes. The most important one is 2,4-dinitrotoluene, also known as 2,4-DNT, DNT, 1-methyl-2,4-dinitrobenzene, benzene 1-methyl-2,4-dinitro-, $C_7H_6N_2O_4$, CAS RN [121-14-2]. The oxygen balance is -114.4% , and the nitrogen content is $15.38\%N$. 2,4-DNT is an intermediate not only in the production of 2,4,6-trinitrotoluene, but also in the production of toluene diisocyanate, an important crosslinking agent for polyurethane polymers, which are used as binders in solid rocket propellants and many other industrial applications. DNT is produced in large quantities, and as a result, poor housekeeping has caused environmental pollution in the proximity of current and former production sites. Environmental cleanup efforts are in progress at many current and former DNT production sites and various cleanup techniques are being evaluated.

DNT has been used as an ingredient in castable explosives for warheads and bombs, although its energy content is less than that of trinitrotoluene. DNT has been proposed or used temporarily in a few rocket propellant and pyrotechnic formulations, mostly patent applications that never matured to actual applications on an industrial scale.

There is so much information on DNT production, applications, and disposal that it would overflow the scope of this book. Sufficient information on DNT is available from other sources. For that reason we abbreviated DNT from the usual data collection format in this book, and the same rationale was applied to 2,4,6-TNT, which is only briefly discussed in the following section.

The isomers 2,3-DNT and 3,5-DNT are rarely formed and have no significance as energetic materials or precursors. At worst, they are encountered as contaminants in 2,4-DNT and 2,4,6-TNT.

3.1.1 Physical Properties of 2,4-Dinitrotoluene

The physical properties of 2,4-dinitrotoluene are summarized in Table 10. See also [53].

Table 10: Physical properties of 2,4-dinitrotoluene.

Property	SI units		Other units	References
Molecular mass	182.1335 g/mol		5.4905 mols/kg	
Melting point	341 K		68 °C	[39]
Density	1.521 g/cm ³			[36]
	1.317 g/cm ³		0.0476 lb/in ³	[49]
Vapor pressure at melting point	0.11 mbar		0.08 mm Hg	[36]
Enthalpy of formation	-66.4 ± 3.0 kJ/mol	-364 ± 16 kJ/kg	-15.87 ± 0.7 kcal/mol	[39]
	-68.2 kJ/mol	-374.7 kJ/kg	-16.31 kcal/mol	[36]
	-54.1 kJ/mol	-297 kJ/kg	-71 cal/g	[49]
Heat of combustion	3552 kJ/mol	19.5 kJ/g	849 kcal/mol	[41]
Heat of fusion	20.12 kJ/mol	0.11 kJ/g	4.81 kcal/mol	[39]
	19.83 kJ/mol	109 kJ/kg	4.74 kcal/mol	[36]
Heat of sublimation at 270–315 K	94.7 ± 2.3 kJ/mol	520 ± 13 kJ/kg	22.63 ± 0.55 kcal/mol	[39]

The vapor pressures of 2,4,6-TNT, 2,4-DNT, and 2,6-DNT have been measured by an electron-capture gas-chromatographic method in a temperature range of 287.15 to 329.65 K for TNT, 277.15 to 344.15 K for 2,4-DNT, and 277.15 to 323.15 K for 2,6-DNT [54]. The temperature dependence of the vapor pressure can be expressed by the following equations:

$$\text{TNT: } \log \left(\frac{p}{\text{Torr}} \right)_{10} = (12.31 \pm 0.34) - (5175 \pm 105) \frac{K}{T}$$

$$\text{2,4-DNT: } \log \left(\frac{p}{\text{Torr}} \right)_{10} = (13.08 \pm 0.19) - (4992 \pm 59) \frac{K}{T}$$

$$\text{2,6-DNT: } \log \left(\frac{p}{\text{Torr}} \right)_{10} = (13.99 \pm 0.18) - (5139 \pm 52) \frac{K}{T}$$

The values for the enthalpy of sublimation are $\Delta H_{\text{sub}}(\text{TNT}) = (23.7 \pm 0.5) \text{ kcal/mol}$, $\Delta H_{\text{sub}}(\text{2,4-DNT}) = (22.9 \pm 0.3) \text{ kcal/mol}$, and $\Delta H_{\text{sub}}(\text{2,6-DNT}) = (23.5 \pm 0.2) \text{ kcal/mol}$. The indicated uncertainties are standard errors.

In the Trauzl lead block, the indentation increase of DNT was 240 cm³/10 g. In the BAM impact sensitivity test at the maximum rating of the machine at 50 Nm there was no reaction. In the BAM friction sensitivity test there was no reaction at the maximum pistil load of 353 N.

The critical diameter of 2,4-DNT was between 3.8 and 5.04 cm. The ideal detonation velocity as a function of density can be calculated from

$$v_D = 4125 + 2270(\rho - 1.0)$$

where v_D is the detonation velocity in m/s and ρ is the loading density in g/cm³.

3.2 2,4,6-Trinitrotoluene

2,4,6-Trinitrotoluene, also known as *sym*-trinitrotoluene, TNT, C₇H₅N₃O₆, CAS RN [118-96-7] is not used as a rocket propellant because it is an explosive. The oxygen balance is -73.9% and the nitrogen content is 18.50% N. It may be used as an additive in rocket propellants as long as the concentration does not exceed 5 mass-% (to stay on the safe side):

TNT is produced by the nitration of toluene with mixed nitric and sulfuric acid in several steps. The trinitration step needs high concentrated mixed acids with free SO₃. Already around 1902, the Germans and the British had experimented with TNT, first prepared by Wilbrand in 1863. Pure 2,4,6-TNT was prepared in 1880 by Hepp, and its structure was established in 1883 by Claus and Becker. By 1914, TNT had become the standard explosive for all armies during World War I, replacing picric acid in this application. The use of a mixture of TNT and ammonium nitrate (AN), called *amatol*, became widespread to relieve temporary shortages of TNT. TNT is underoxidized (oxygen balance -73.9%) so that the addition of AN as an oxidizer results in near-stoichiometric compositions with higher energy output. The physical properties of TNT are summarized in Table 11. See also [55, 56].

The detonation velocity of confined TNT was 6900 m/s at a packing density of 1.60 g/cm³. In the Trauzl lead block, the indentation increase caused by TNT was 300 cm³/10 g. In the BAM impact sensitivity test the 50% point was at 15 Nm. In the BAM friction sensitivity test there was no reaction at the maximum pistil load of 353 N.

4 Nitrophenols

The heats of combustion of *o*-, *m*-, and *p*-nitrophenol, C₆H₄OH(NO₂), are 2883, 2863, and 2871 kJ/mol (689.1, 684.4, and 686.2 kcal/mol), respectively. The heat of combustion of 2,4-dinitrophenol, C₆H₃OH(NO₂)₂, is 2711 kJ/mol (648 kcal/mol) [41]. Nitrophenols have been used as blocking agents for polymers in liners for solid propellant rocket motors.

4.1 2,4,6-Trinitrophenol (Picric Acid)

2,4,6-Trinitrophenol, picric acid, also known as C₆H₂OH(NO₂)₃, C₆H₃N₃O₇, CAS RN [88-89-1] is a very sensitive explosive that has been the cause of numerous accidents in munitions factories and munitions storage magazines. It is not suitable as a rocket propellant:

4.1.1 History of Picric Acid Usage

In 1885, Turpin found picric acid to be a suitable explosive as a replacement for black powder. In 1888, black powder was replaced by picric acid in British munitions under the name Lyddite. In Russia, Panpushko prepared picric acid in 1894 and soon realized its potential as an explosive. Eventually, picric acid and its salts were accepted in many industrialized countries as the basic explosive for some military uses and were used for several decades until eventually being replaced by TNT. Picric acid has been used as a dye for fabrics and as an analytical reagent for identification of amino compounds, typically for naturally occurring alkaloids.

Various picrates of heavy metals are used as primary, stab-sensitive explosives in percussion caps due to their high impact sensitivity and detonating power. The ammonium salt of picric acid has been used as an explosive for the filling of artillery shells, similar to the parent acid itself.

4.1.2 Properties of Picric Acid

Picric acid forms yellow crystals that are soluble in water. With a molecular mass of $229.1 \text{ g/mol} = 4.365 \text{ mol/kg}$, the enthalpy of formation is $-944.3 \text{ kJ/kg} = -216.3 \text{ kJ/mol} = -51.7 \text{ kcal/mol} = -225.7 \text{ kcal/kg}$. The heat of combustion of 2,4,6-trinitrophenol is $2599 \text{ kJ/mol} = 621.1 \text{ kcal/mol}$ [41].

4.2 Styphnic Acid

2,4,6-Trinitro-1,3-benzenediol, also known as styphnic acid, trinitroresorcinol, $\text{C}_6\text{H}(\text{OH})_2(\text{NO}_2)_3$, $\text{C}_6\text{H}_3\text{N}_3\text{O}_8$, CAS RN [82-71-3] forms yellow crystals. The compound can be used as a yellow dye for fabrics similar to picric acid. Styphnic acid can be prepared by the nitration of resorcinol with a mixture of nitric and sulfuric acids. Several styphnates are used as additives for solid propellant formulations. Lead styphnate is stab-sensitive and can be used in percussion initiators and in blasting caps. Styphnates are sometimes called trinitroresorcinates or tricinates.

5 Picramide

2,4,6-Trinitroaniline, also known as picramide, $\text{C}_6\text{H}_4\text{N}_4\text{O}_6$, CAS RN [489-98-5] can be prepared by reacting trinitrochlorobenzene with ammonia or by nitration of 4-nitroaniline:

It is a very sensitive explosive with a detonation velocity of 7300 m/s at $\rho = 1.72 \text{ g/cm}^3$ and is not used as a rocket propellant. Picramide has a molecular mass of 228.12 g/mol = 4.384 mol/kg, density of 1.792 g/cm^3 , and a melting point of 461 K = 188 °C = 370 °F. The heat of formation is $-368.1 \text{ kJ/kg} = -84.0 \text{ kJ/mol} = -20.1 \text{ kcal/mol} = -88.0 \text{ kcal/kg}$.

If one combines two picramide entities as in a biphenyl compound, one obtains 3,3'-diamino-2,2',4,4',6,6'-hexanitrobiphenyl, dipicramide, DIPAM, CAS RN [17215-44-0], which is a powerful explosive.

6 Tetryl

2,4,6-Trinitro-phenylmethylnitramine, also known as tetryl, tetranitromethylanilin, *N*-picryl-*N*-methylnitramine; benzenamine, *N*-methyl-*N*,2,4,6-tetranitro-; $\text{C}_7\text{H}_5\text{N}_5\text{O}_8$, CAS RN [479-45-8], with a molecular mass of 287.14 g/mol = 3.483 mol/kg, is a primary explosive and often used in blasting caps and primers. The detonation velocity is 7570 m/s at $\rho = 1.71 \text{ g/cm}^3$. The lead block indentation is $410 \text{ cm}^3/10 \text{ g}$. It is not used in rocket propellants. Tetryl has a density of 1.73 g/cm^3 , a melting point of 402.6 K = 129.5 °C = 265 °F, a heat of formation of $+69.7 \text{ kJ/kg} = +20.0 \text{ kJ/mol} = +4.78 \text{ kcal/mol} = +16.7 \text{ kcal/kg}$, and a heat of fusion of $19.1 \text{ kcal/kg} = 5.48 \text{ kcal/mol} = 1.31 \text{ kcal/mol} = 80 \text{ kJ/kg}$. Other sources gave a heat of fusion at 400.5 K of $\Delta H_{\text{fus}} = 6.18 \pm 0.07 \text{ kcal/mol}$ and a heat of decomposition at 445 K of $-94 \pm 2 \text{ kcal/mol}$.

7 Nitronaphthalenes

Nitronaphthalenes, ranging from mononitronaphthalene to tetranitronaphthalene, and nitronaphthols, ranging from mononitronaphthol to tetranitronaphthol, are described in detail in Fedoroff's *Encyclopedia of Explosives and Related Items*, Vol. 8, p. N7-N20. Nitronaphthalenes have been evaluated as additives to other, more commonly used explosives like TNT to lower the melting point for castable explosives. There are no advantages to the use of nitronaphthalenes as rocket propellants.

The heats of combustion of nitronaphthalene, 1,5-dinitronaphthalene $\text{C}_{10}\text{H}_6(\text{NO}_2)_2$, and trinitronaphthalene $\text{C}_{10}\text{H}_5(\text{NO}_2)_3$ are 4981, 4831, and 4641 kJ/mol (1190.5, 1154.6, and 1109.3 kcal/mol), respectively [12, 41].

Nitro Compounds

The chapters in *Encyclopedia of Oxidizers*, deal with nitro compounds and nitric acid esters, also called nitrate esters. The topic of nitro compounds had to be distributed over four subchapters, because a single chapter would have been very large, which would have made it more difficult for readers to find information on a specific compound; in addition, it would have been difficult to arrange 30 chapters among 5 subvolumes in such a way that each subvolume is about the same size. That spatial arrangement was made easier by dealing with smaller chapters.

This chapter, “Nitro Compounds,” serves as an introduction to the individual chapters, titled “Nitromethanes,” “Nitroaliphatic Compounds,” and “Nitroaromatic Compounds,” and to some extent it also relates to the chapter on nitrate esters. Very few of these compounds contain excess oxygen and are properly listed in this volume under oxidizers. Even fewer compounds are exactly balanced for combustion to carbon dioxide, nitrogen, and water, leaving behind neither unused oxygen nor unburned hydrogen or carbon. The majority of nitro compounds discussed here are oxygen deficient and would require additional oxygen to achieve complete combustion to carbon dioxide, nitrogen, and water. In practice, however, it is not necessary to achieve complete combustion to carbon dioxide because combustion to carbon **monoxide** may be sufficient to obtain a good rocket monopropellant. Nevertheless, oxygen balances are commonly calculated for complete combustion to carbon dioxide instead of partial combustion to carbon monoxide. Very few organic compounds are true oxidizers with excess oxygen beyond that consumed by burning structural carbon to CO or CO₂ and burning all attached hydrogen (if any) to water. Several organic true oxidizers are included in this chapter, but most of the others are underoxidized and would be better characterized as potential monopropellants or partially oxidized fuels than as oxidizers. We do not wish to separate this group of chemicals based on their oxygen balance, but we discuss their physical and chemical properties together here in the same oxidizer chapter. Many of these compounds undergo autodecomposition when heated, and many are sensitive to stimuli that will trigger explosions. Investigations of decomposition in an academic setting are discussed here, while actual applications as monopropellants in rockets, gas generators, or torpedoes will be discussed in *Encyclopedia of Monopropellants*.

1 General Properties of Nitro Compounds as a Family Group

1.1 Oxygen Balance of Oxygen-rich Organic Compounds

An important parameter in judging organic oxidizers and monopropellants is their **oxygen balance**.

Oxygen balance is defined as the number of oxygen equivalents per unit of propellant when a sample burns or detonates and all atoms in the molecule finally convert into the following molecules as combustion products:

Therefore, when the empirical formula of a propellant is represented by $\text{C}_a\text{H}_b\text{O}_c\text{N}_d$, the reaction for the combustion or explosion is expressed as follows:

Organic oxygen-rich compounds having the general formula $\text{C}_a\text{H}_b\text{O}_c\text{N}_d$ are of interest as oxidizers for rocket propellants. Very few energetic materials happen to be stoichiometrically balanced, theoretically giving only carbon dioxide, nitrogen, and water as exhaust products. Most are underoxidized with an oxygen balance (*OB*) of < 100 , and a few (most of those discussed here) have an excess of oxygen ($OB > 100$), which qualifies them as organic oxidizers.

The definition of oxygen balance (*OB*, in %) is given by the following equation:

$$OB = \left(c - 2a - \frac{b}{2}\right) \frac{1600}{M}$$

where M is the molecular mass of the compound, a is the number of carbon atoms, b is the number of hydrogen atoms, and c is the number of oxygen atoms. The presence of nitrogen has no effect on the oxygen balance since it is assumed to be non-reactive and it all converts to dinitrogen N_2 . In calculating the molecular mass, one should use the natural isotope composition of hydrogen (including a natural distribution of deuterium) instead of the atomic mass of pure H, but the difference is only minor.

For $\text{C}_a\text{H}_b\text{O}_c\text{N}_d\text{X}_x$ compounds that contain halogens X (chlorine, fluorine) in addition to CHNO, the *OB* formula becomes

$$OB = \left(c + \frac{x}{2} - 2a - \frac{b}{2}\right) \frac{1600}{M}$$

Since solid propellants consist of binder, oxidizer, and some additives, x , y , z , and u in $\text{C}_x\text{H}_y\text{O}_z\text{N}_u$ are calculated from the molecular formula of each ingredient and the composition percentage. For example, $\text{C}_x\text{H}_y\text{O}_z\text{N}_u$ of the propellant composed of a mass ratio of oxidizer : binder of 80 : 20 is calculated using the molecular formula of the oxidizer ($\text{C}_a\text{H}_b\text{O}_c\text{N}_d$) and the binder ($\text{C}_e\text{H}_f\text{O}_g\text{N}_h$) as follows:

$$x = 0.8a + 0.2e$$

$$y = 0.8b + 0.2f$$

$$z = 0.8c + 0.2g$$

$$u = 0.8d + 0.2h$$

Halogens are oxidizers with an equivalence half that of oxygen. Use of a computer to calculate the possible number of organic chemical compounds containing only C, H, N, and O reveals that the number of theoretically possible compounds decreases from compounds with a small *OB* (fuels) to compounds with a large *OB* (oxidizers) [1]. For an initial survey, the search was restricted to compounds containing no more than a total of 12 atoms.

Sometimes the *OB* is also expressed as a fraction with the symbol λ instead of as a percent number.

1.2 Nomenclature of Nitro Compounds and Nitrate Esters

The commonly used names nitroglycerin and nitrocellulose are incorrect because these are not nitro compounds but the nitric acid esters of glycerol, correctly called glycerol trinitrate, and cellulose, correctly called cellulose nitrate, but hardly anybody recognizes them by those legal names. Compounds that contain an NO group connected to the organic moiety via the O atom instead of the N atom are not nitro compounds. They are the esters of nitrous acid HONO, sometimes called nitrites, and they are isomers of nitro compounds, but quite different in chemical properties and rarely used as rocket propellants. In nitrous acid esters (alkyl nitrites) and nitric acid esters (alkyl nitrates), the NO₂ or NO₃ group is connected to the organic skeleton by an oxygen —C—O—N— bridge. Alkyl nitrites are less stable and less energetic than alkyl nitrates and have not achieved any practical importance as propellant ingredients. Nitroalkanes and alkyl nitrates are very energetic compounds, sometimes so energetic and so sensitive (too energetic and too sensitive) that the borderline between liquid explosive and liquid propellant becomes blurred.

Nitro compounds are only those that contain the —NO₂ group connected to an organic rest via the N atom, and not via an —O— bridge. A different and special category are the nitramines, where the nitro group is connected to the organic skeleton, not directly but via a nitrogen atom that may or may not carry a hydrogen atom. These compounds have good thermal stability and form many of the high explosives currently in use. In combination with proper phlegmatizers and binders, they also form the key ingredients of a group of solid rocket and gun propellants called nitramine propellants. Nitramines as chemicals and propellant ingredients are discussed in *Encyclopedia of Liquid Fuels*, in the chapter “Nitramines.”

The three chapters “Nitromethanes”, “Nitroaliphatic Compounds” and “Nitroaromatic Compounds” contain information on the physical and chemical properties of nitro compounds, including information on their safety properties, which need to be known and respected, literally for the sake of survival. The mechanisms and kinetics of thermal and controlled catalytic decomposition and combustion will be discussed there, while applications as monopropellants are covered in *Encyclopedia of Monopropellants*. Safety properties such as detonability and shock sensitivity will be dis-

cussed in sections immediately following descriptions of the physical and chemical properties of these compounds. This will include a few sections on the detonability and shock sensitivity of mixtures containing liquid nitro compounds. Future parts of this *Encyclopedia of Rocket Propellants* will also contain extensive chapters on solid nitro compounds and nitrate esters such as those used in solid propellants and energetic additives, in particular the volume on double-base solid propellants, which are mostly derived from nitrated cellulose and glycerol. Other nitrate esters are used as energetic plasticizers for double-base propellants.

Nitro compounds and nitrate esters are produced by a variety of nitration reactions. Nitration is a fundamental chemical process by which less reactive hydrocarbons or alkanols are converted to energetic compounds. Nitration is an important chemical reaction not only for the production of rocket propellants and explosives but also for the chemical process industry in general, by which many intermediates are produced that are eventually converted to dyes, pharmaceuticals, polymers, or pesticides. Several books are available that summarize the kinetics and industrial applications of nitration reactions and that deal with nitration in general, not necessarily for the synthesis of propellants or explosives [2, 3].

Nitrogen Dioxide

Coverage of nitrogen oxides had to be spread out over seven chapters because a single chapter on the topic would have been very large and would have made it more difficult for readers to find information on a specific compound. In addition, arranging 30 chapters among 5 subvolumes in such a way that each subvolume was about the same size represented a formidable challenge. A book with smaller chapters made our task easier.

The other six chapters in this series are titled “Nitrogen Oxides,” “Nitrous Oxide,” “Nitric Oxide,” “Dinitrogen Trioxide,” “Dinitrogen Tetroxide,” and “Dinitrogen Pentoxide.”

Nitrogen dioxide, NO_2 , CAS RN [10102-44-0], exists mostly as a gas as a product of dissociation of dinitrogen tetroxide or a product of oxidation of nitric oxide. Nitrogen dioxide is a free radical, which explains its high reactivity with a large number of compounds. It has an unpaired electron. When condensed, it dimerizes to form N_2O_4 and loses its red color.

Nitrogen commonly forms several different oxides with oxygen, depending on the state of oxidation of the central atom, nitrogen. The state of oxidation of nitrogen can be +1, +2, +3, +4, +5, or +6. The correct names of the six oxides are nitrous oxide, N_2O , nitric oxide, NO , dinitrogen trioxide, N_2O_3 , nitrogen dioxide, NO_2 , dinitrogen pentoxide N_2O_5 , and nitrogen trioxide NO_3 . The current chapter is on nitrogen dioxide, NO_2 , which is used mostly in its dimeric form, dinitrogen tetroxide, N_2O_4 , which can be stored as a liquid at room temperature. The state of oxidation of nitrogen in dinitrogen tetroxide is the same as that in nitrogen dioxide. Nitrogen forms at least six covalently bound oxides, N_2O , NO , N_2O_3 , NO_2 , N_2O_5 , and NO_3 , which are all thermodynamically unstable with regard to their tendency to decompose to dinitrogen and dioxygen. Nitrogen dioxide dimerizes by way of $\pi^*-\pi^*$ -interactions. Although all nitrogen oxides (in the gas phase) have positive enthalpies of formation, they still are not intrinsically unstable.

As far as rocket propellants are concerned, the first two oxides in this family of nitrogen oxides, nitric oxide and nitrous oxide, have not found the same widespread application as dinitrogen tetroxide and its mixtures with dinitrogen trioxide or nitric acid.

Many of the physical properties of pure NO_2 are difficult to determine because the gas may contain an equilibrium amount of N_2O_4 or even NO (at higher temperatures). At higher temperatures, NO_2 dissociates reversibly into nitric oxide, NO , and dioxygen, O_2 .

1 Natural Occurrence of Nitrogen Dioxide

Other than as a noxious atmospheric pollutant in Earth's atmosphere, nitrogen dioxide has been identified on other planets and in comets. In search of extraterrestrial resources that could be used as rocket propellants or sources of breathing oxygen, coming upon an extraterrestrial polar ice cap that consists mostly of frozen nitrogen dioxide and dinitrogen tetroxide would be a real bonanza.

Nitrogen dioxide has been identified in the atmosphere of Mars, which has an overall oxidizing environment, indicated by the fact that most iron on the surface of Mars is in its trivalent state, and that gives Mars its distinct rust brown color that is visible even to the unaided eye from Earth. The current Martian atmosphere contains only 0.2 mbar of nitrogen. The lower atmosphere of Mars contains 1.7 ppb of NO. Nitrogen dioxide is a highly photolabile gas and will be photodissociated by visible and UV radiation on Mars and anywhere else in the universe. The photochemical equilibria of nitrogen oxides on Mars have been computed from the observational upper limits on the NO and O₂ abundances [1, 2].

2 Production of Nitrogen Dioxide

Nitrogen dioxide is a major industrial product as an intermediate in the production of nitric acid, most of which goes into fertilizer production in the form of ammonium nitrate. Only very little nitrogen dioxide is side-tracked from the process stream and condensed in the form of dinitrogen tetroxide to be used as a rocket propellant. The main method for the production of nitric acid is the catalytic combustion of ammonia over a platinum gauze (Ostwald process)

For small quantities of NO₂ to be prepared in the laboratory, copper shavings can be reacted with concentrated (not fuming) nitric acid while passing an excess of air over the reacting mixture to convert all NO to NO₂:

The reaction of nitric oxide with oxygen has been investigated experimentally for many years and is of great technical importance. It has two unusual properties: **(1)** it is kinetically a third-order reaction and **(2)** the velocity constant, *k*, decreases with increasing temperature [3]. Computational chemistry has supported the experimental measurements [4]. The best estimate of the activation energy was 6.47 kJ/mol.

An easy method of preparing NO_2 in small quantities is the decomposition of carefully dried lead(II) nitrate at 723 K (450 °C):

A clean laboratory method for preparing small samples of NO_2 is the reaction between potassium nitrate and nitrosyl bisulfate:

The reaction of dinitrogen trioxide (N_2O_3) with dinitrogen pentoxide (N_2O_5) gives dinitrogen tetroxide. The only problem is that N_2O_5 is not stable and has to be prepared immediately beforehand. A mixture of nitric acid and phosphorus pentoxide behaves as dinitrogen pentoxide. When these constituents are mixed, nitrogen dioxide is evolved:

Acidifying sodium nitrite with nitric acid will liberate nitrous acid, which promptly decomposes to nitric oxide that with additional air will form nitrogen dioxide:

Preparing NO_2 from the elements, as in air, by passing the gas through an electric discharge is the process that takes place on a global scale in nature in lightning discharges. The industrial version of this process, the Birkeland process, was practiced until 100 years ago in countries with ample hydroelectric power prior to the invention of the Haber-Bosch process for ammonia production and the Ostwald process for ammonia oxidation.

Oxides of nitrogen available from commercial sources are often not pure enough for spectroscopic studies. It is difficult to obtain pure oxides of nitrogen free from water and other oxides of nitrogen. There are convenient methods for preparing oxides of nitrogen and purifying them in the laboratory in small quantities just enough for spectroscopic studies [5].

It sometimes helps to purify NO before converting it to NO_2 [6]. This report also described methods for the detection and measurement of residual impurities in the final products.

3 Physical Properties of Nitrogen Dioxide

The physical properties of nitrogen dioxide are invariably tied to the physical properties of dinitrogen tetroxide and its dimer with which it exists in equilibrium over a wide temperature range from below its boiling point to above 298 K. Pure nitrogen dioxide exists only at temperatures above 420 K when most of the N_2O_4 is dissociated, but at

the same temperature NO_2 starts decomposing into NO and O_2 . So it is really difficult to obtain pure NO_2 in the gaseous state for physical measurements. The molecular mass of nitrogen dioxide is 46.0055 g/mol.

3.1 Optical Properties of Nitrogen Dioxide

3.1.1 UV/Visible Absorption Spectra of Nitrogen Dioxide

A thorough knowledge of the absorption spectra of nitrogen dioxide allows us to develop analytical methods for detecting NO_2 in the atmosphere of working rooms or propellant storage areas in the parts-per-million (ppm) or even parts-per-billion (ppb) range. The absorption spectra also help us to determine N_2O_4 and NO_2 dissociation equilibria and identify intermediates in the reactions of NO_2 and N_2O_4 with hypergolic fuels, reactions that determine the ignition delay, an important parameter for rocket applications. Rocket propellant storage areas where dinitrogen tetroxide (NTO) is stored must be monitored for potential leakage. Spectral methods provide the best methods for area surveillance and can trigger an alarm when a leak is detected. The air in work rooms where NTO is handled must be monitored continuously to comply with government regulations for maximum allowable exposure of working personnel to NO_2 vapors. A large selection of spectrographic equipment is available to serve this purpose. Accurate absorption cross sections of atmospheric pollutants like NO_2 or O_3 must be known to correctly interpret the flood of remote sensing data that are beamed down from environmental satellites, looking at the atmosphere from above. The spectral overlap of N_2O_4 absorption with NO_2 absorption in the near-UV interferes with the accurate experimental determination of the absorption cross section of NO_2 at wavelengths shorter than 400 nm. To remove and compensate for the contribution of N_2O_4 from studies of NO_2 profiles in the atmosphere, either the form of the temperature dependence of the equilibrium constant for the equilibrium of N_2O_4 and NO_2 , $K_p(T)$, must be known or K_p must be measured at the specific temperature of interest.

Unfortunately, not all absorption cross-section data were reliable, and a critical literature review was conducted to eliminate data whose accuracy was dubious. The available laboratory measurements of UV-vis (240–790 nm) absorption cross sections of O_3 and NO_2 were critically reviewed taking into account the variation of the cross sections with temperature (in the 200–300 K range) and with total pressure (<101 kPa) [7].

It would be best to calibrate satellite-borne instruments in a large atmospheric simulation chamber with known concentrations of NO_2 and O_3 . The dependence of the absorption cross section on temperature and pressure also enters the calibration and data reduction. The NO_2 absorption cross sections in the 240–790 nm region (Figure 1) can be separated into two principal systems: the D-X band system below 250 nm and the broad B-X and A-X band systems between 300 and 790 nm, with a maximum at around 400 nm. Due to interactions the forbidden C-X transition can also contribute

Figure 1: NO₂ UV-visabsorption spectrum at room temperature. (Reprinted and modified from [7], with permission from © 2003 Elsevier; permission conveyed through RightsLink.)

to the visible spectrum of NO₂. The shape of the visible absorption spectrum is close to that of a Gaussian bell-shape function, but there is a lot of spectral fine structure superimposed on it. Due to the complexity of the excited electronic states of NO₂, it is almost impossible to predict its spectrum from molecular quantum theory within experimental accuracy. The average absorption cross section of NO₂ at room temperature collected and averaged from 14 different publications was 4.50×10^{-17} in the range 400–500 nm and 2.77×10^{-17} in the range 400–500 nm with a standard deviation (1σ) of $\pm 2.4\%$.

The electronic absorption spectra of NO₂/N₂O₄ equilibrium mixtures were measured in non-polar and polar solvents [8]. In non-polar solvents, the spectra were very similar to those of NO₂/N₂O₄ equilibrium mixtures in the gas phase. However, in solvents with unshared electron pairs, particularly in ethers, esters, ketones, and tertiary amines, complex multi-band spectra were observed at room temperature. These are assumed to be of the electron donor-electron acceptor type molecular complex (Lewis adducts).

Because of the equilibrium $2\text{NO}_2 \rightleftharpoons \text{N}_2\text{O}_4$, it is difficult to separate the absorption spectra of NO₂ and N₂O₄ in the vapor phase. Measurements at different pressures showed the increase and decrease of absorption bands. Bands increasing with pressure belong to N₂O₄, and bands decreasing with pressure belong to NO₂. Optical density ($\log I_0/I$) curves were obtained of the equilibrium $2\text{NO}_2 \rightleftharpoons \text{N}_2\text{O}_4$ mixture over the range 2400–5000 Å [9]. From three absorption curves taken at a constant temperature of 298 K (25 °C), three total pressures ($P = 33, 126, \text{ and } 307 \text{ mm Hg}$), and three different absorption cell path lengths, the spectra of the two compounds could be separated mathematically (Figure 2).

Figure 2: Absorption coefficients and resolved absorption spectra of nitrogen dioxide and dinitrogen tetroxide at 298 K. (Republished and modified from [9], with permission of © 1952 American Institute of Physics; permission conveyed through Copyright Clearance Center Inc.)

No fine structure was recorded in the spectrum of N_2O_4 . This is probably due not to its absence but rather to extreme fineness, which may prove almost impossible to resolve. The sharp, well-defined structures in the NO_2 spectrum do not appear in the N_2O_4 spectrum, probably because of the large number of closely spaced energy levels introduced into the molecule by the formation of the weak N—N bond. The low energy of the N—N bond stretching as well as its possible low-energy torsional vibration probably gives rise to a fine structure, resulting in further broadening.

One might consider NO_2 a free radical because it carries a free electron that is also responsible for its deep red color because it absorbs light in the visible region of the spectrum, where its dimer N_2O_4 does not. The electronic energy levels excited by visible light and UV have been studied extensively because a better understanding of these energy levels will help the interpretation of reactivity of NO_2 and dissociation of NO_2 under reacting conditions in a rocket engine and in the upper atmosphere.

The extinction coefficient of NO_2 was measured in the spectral range from 185 to 410 nm as a function of temperature between 235 and 298 K [10]. To correct for the effect of dimer absorption, the extinction coefficient of N_2O_4 has also been measured.

NO_2 concentrations in the air can be measured by fluorescence spectroscopy. The mean lifetime of fluorescence of NO_2 vapor was measured at pressures in a range of 12 to 0.6 μm using a direct method [11]. A linear dependence of lifetime on pressure was found, and extrapolation to zero pressure gave 44 μs for the lifetime in absence of collisions. The fluorescence spectrum in the region 4600–8000 Å was photographed with 4358 and 5461 Å excitation, with somewhat different results, indicating two excited electronic levels, one of which is not connected optically to the normal state and which is responsible for the long-lived fluorescence.

The excitation spectrum for the ν_2 fluorescence mode of NO_2 was measured throughout its visible absorption spectrum [12]. The spectra showed several narrow regions where the ν_2 fluorescence intensity was about two orders of magnitude larger than that found elsewhere.

Nitrogen dioxide has absorption features in the ultraviolet, blue, and green regions of the optical spectrum. Values of total columnar NO_2 range from 0.4×10^{-3} to about 5×10^{-3} cm NO_2 at standard temperature and pressure (STP) and yield optical depths from 0.008 to 0.087 at 390 nm, the wavelength of maximum absorption [13].

The absorption cross section of NO_2 has been measured above the 3979 Å predissociation limit in the region of 3920 and 3950 Å and in the discretely structured areas around 4112 and 4140 Å [14, 15]. The measurements of the absolute-absorption cross section of NO_2 were made from 3910 to 3925 Å, 3948 to 3953 Å, 4107 to 4115 Å, and 4131 to 4145 Å. All measurements were performed at 300 K and at several pressures of N_2 diluent ranging from 20 to 400 mm Hg. Measurements were also performed from 4107 to 4112.5 Å and 4132 to 4143 Å at 251 K. Spectra were taken in a dual-beam arrangement using a tunable, pulsed dye laser with 0.05 bandwidth. This represented an improvement of at least a factor of three over the resolution employed in previous studies. On the basis of the onset of rotational diffuseness, other investigators placed the predissociation limit at 3979 Å. Below 3979 Å, the spectra were continuous with occasional diffuse rotational lines superimposed. The spectra taken above 4100 Å revealed a wealth of structural complexity. Only slight variations in the measured cross sections were observed between 300 and 250 K. An example of a high-resolution spectrum of NO_2 for a very narrow frequency range from 4138.3 to 4143.3 Å is shown in Figure 3. There are several more high-resolution spectra like this one in the report.

The absorption cross sections of NO_2 have also been measured in a wavelength range of 200–700 nm at 298 K with a spectral resolution of 0.04 nm [16]. The data were acquired digitally, allowing post-processing by integration over different wavelength intervals and their use in solar photolysis calculations.

Figure 3: Absolute absorption cross section of NO_2 in air from 4138.3 to 4143.3 Å at 300 K. (Reproduced and modified from [15] Koffend et al. 1987.)

The spectral region from 440 to 460 nm is of special interest for remote sensing applications. The interpretation of absolute NO_2 absorption cross section in the 440- to 460-nm region at different temperatures is complicated by the coexistence of NO_2 and its dimer N_2O_4 . In one experiment, both NO_2 and N_2O_4 absorption features were observed and different approaches were used to obtain the partial pressure of NO_2 , giving a new estimate of the $2\text{NO}_2 \rightleftharpoons \text{N}_2\text{O}_4$ equilibrium constant [17]. Within experimental errors, the overall shape of the spectrum did not show a dependence on temperature, but only a slight increase of a few maxima and a decrease of other maxima and of the minima were observed when the temperature was lowered.

Errors in the cross sections of $\text{NO}_2/\text{N}_2\text{O}_4$ reported by various authors at low to room temperature may be between $\pm 3\%$ and $\pm 8.8\%$. Of these errors, up to $\pm 3.5\%$ was contributed by errors in the equilibrium constant, K_p , in those measurements where the pressure was above 0.1 mbar. For example, IR measurements of the partial pressure of NO_2 ignored the dependence of absorption on total pressure. There are no measurements of NO_2 cross sections below 230 K. Extrapolation of these cross sections to analysis of measurements of NO_2 at the low temperatures of the Arctic and Antarctic stratosphere is inaccurate. For satisfactory analysis of polar spectra, the NO_2 cross sections should be measured at temperatures down to 190 K with a relative accuracy of $\pm 1\%$. This difficult experiment would need a cell of minimum length 32 m whose length can be adjusted [18]. The optimum experiment might therefore simultaneously measure the visible and IR spectra.

Based on measurements of NO_2 absorption cross sections between 300 and 500 nm at ambient temperature with improved experimental conditions – low gas pressures, long absorption paths, suitable absorbance values, and narrow spectral bandwidths of 0.01 nm – it was found that in the photolysis region below 400 nm, absorption cross sections were larger than those previously published, suggesting that the photodissociation coefficient calculated from other data sets may have been underestimated [19]. In the structured region of the spectrum above 400 nm, improvement of the resolution gave more precise values useful for future optical measurements in the Earth's atmosphere.

Two different single-mode diode lasers were used to record high-resolution absorption spectra of NO_2 (dilute in Ar) near 670.2 and 394.5 nm over a range of temperatures (296 to 774 K) and total pressures (2.4×10^{-2} to 1 atm) and to measure variations of the spectral absorption coefficients with temperature and pressure [20, 21].

Previous experiments in the 400- to 500-nm region [19] have been extended to the 200- to 400-nm region to determine the absorption cross sections of NO_2 at 220 K [22]. The NO_2 and N_2O_4 cross sections were obtained simultaneously from a calculation applied to the data resulting from measurements at low pressures. A comparison between the NO_2 cross sections at 220 K and at ambient temperature showed that the low-temperature cross sections are generally lower, except in the region of the absorption peaks. Other investigators have measured the absorption cross sections of NO_2 with high spectral resolution over a wider temperature range [23].

3.1.2 Infrared Absorption Spectra of Nitrogen Dioxide

The NO_2 free radical plays an important role in the chemistry of Earth's atmosphere. In the troposphere, NO_2 is the main source of ozone and has an active role in the urban photochemical pollution. Accurate measurements of NO_2 concentrations in the atmosphere at different altitudes and different times of the day are important and depend on the exact knowledge of the absorption cross sections of NO_2 at all wavelengths. NO_2 and N_2O_4 may also be carried in the atmosphere adsorbed to aerosol particles. Detection of N_2O_4 leaks in propellant storage areas would also be possible by IR beam attenuation at specific wavelengths.

3.1.3 Infrared Absorption Spectra of Gaseous Nitrogen Dioxide

Absorption coefficients of NO_2 were measured at a number of wavelengths in the spectral region 1080–2700 Å with a resolution of 0.2 Å by a photoelectric method [24]. Several bands observed in the region 1080–1200 Å fitted a Rydberg series, and its convergence limit at 11.62 eV was interpreted as the second ionization potential of NO_2 . The first ionization potential was found to be 9.78 eV by the photoionization method. The ionization continuum showed a break at 10.83 eV, which may have been due to a dissociative-ionization process.

The IR spectrum of the ν_1 band of $^{14}\text{N}^{16}\text{O}_2$ has been recorded with a resolution of about 0.025 cm^{-1} in the region extending from 1480 to 1270 cm^{-1} [25]. From about 1350 cm^{-1} , the absorption became progressively weaker, and no absorption could be detected below the band origin located at 1319 cm^{-1} . Because series with low values of K_a could not be measured, constants that depend strongly upon the molecular asymmetry could not be determined.

Using a Fourier transform spectrometer coupled to a multiple reflection cell, high-resolution NO_2 absorption cross sections were obtained at 0.05 cm^{-1} in the near-IR region ($10800\text{--}15100\text{ cm}^{-1}$) and at 0.1 cm^{-1} in the visible region ($13800\text{--}26000\text{ cm}^{-1}$), under various pressure conditions (pure NO_2 and NO_2 /air mixtures) and at three temperatures (220, 240, and 294 K) [26]. The effects of temperature and pressure on the NO_2 cross sections revealed a decrease of the absorption at the maxima of the absorption bands and an increase at the minima with increasing temperature. The absorption cross-section values obtained at 294 K are plotted in Figure 4 (low resolution) and Figure 5 (high resolution) for the whole spectral region, showing the presence of high-resolution structures in the NO_2 spectrum. The temperature effect is illustrated on a small part of the spectrum at an expanded scale, shown in the insert box. See also [5].

Fourier transform infrared (FTIR) spectra of NO and NO_2 were used for the analysis of NO in mixed oxides of nitrogen (MON) [27]. The NO_2 absorption peaks at 2888.8 and 2918.7 cm^{-1} were selected for the calibration curve.

3.1.3.1 Infrared Absorption Spectra of Frozen or Matrix-Isolated Nitrogen Dioxide

Ordinarily, if NO_2 is cooled slowly and without dilution, it will have a chance to dimerize and the condensate would be mostly N_2O_4 . However, if the gas is highly diluted and flash frozen, the dimerization equilibrium does not have a chance to establish itself and the condensate will be mostly NO_2 . In those cases, it is difficult to separate the spectra of NO_2 and N_2O_4 .

The IR spectrum of frozen nitrogen dioxide was studied in carbon dioxide, argon, oxygen, nitrogen, nitrous oxide, and hydrogen matrices, and in the pure state [28]. Isolation of the monomer was favored by the use of high dilution and slow deposition rates and a rigid matrix (CO_2 as opposed to Ar). Sixteen bands were observed, five of these occurred in the ONO bending region around 750 cm^{-1} , three in the NO_2 symmetric stretching region around 1280 cm^{-1} , seven in the NO_2 asymmetric stretching region around 1740 cm^{-1} , and one at 1829 cm^{-1} . The relative intensities of these bands were largely dependent on the conditions of deposition (choice of matrix, dilution ratio, window temperature, and deposition rate). When the sample was warmed from a liquid helium temperature to a liquid nitrogen temperature, new bands appeared in the neighborhood of 1740 cm^{-1} that were assumed to be caused by the dimer. Regardless of the matrix or mode of deposition, when the stable dimer was present, two bands were always observed in the 1740-cm^{-1} region. Some bands were assigned to the asymmetrical isomer ONO-NO_2 . The argument in favor of the existence of a dimer of this structure was supported by absorption bands at 787 cm^{-1} (ONO bend), 1290 cm^{-1} (NO_2 symmetric stretch), 1645 cm^{-1} (NO_2 asymmetric stretch), and 1829 cm^{-1} (N=O stretch).

3.1.4 Raman Spectra of Nitrogen Dioxide

The Raman spectrum of NO_2 excited at 355 nm was found to be dominated by bands containing up to six quanta of the bending vibration and four quanta of the symmetric stretch, with an almost complete absence of bands containing asymmetric stretch quanta [29]. These results were interpreted within a time-dependent view to provide insight into the predissociation dynamics of NO_2 .

3.2 Microwave Spectra of Nitrogen Dioxide

Complete knowledge of the microwave spectra of NO_2 would help in identifying NO_2 in interstellar gas and on planetary bodies. If NO_2 (and N_2O_4) was found on other planets, it would be a welcome *in situ* resource to use as a rocket propellant (although the atmosphere would not be very breathable).

Some 69 microwave absorption lines from three isotopic modifications of NO_2 have been observed and identified [30]. This spectrum has been completely analyzed in terms of moments of inertia, magnetic fine structure, and centrifugal distortion. The results obtained for $^{14}\text{N}^{16}\text{O}_2$ were as follows: rotational constants, odd electron expec-

tation values with respect to N nucleus, and reduced spin-rotation coupling constants. The magnetic coupling constants were discussed in terms of a simplified electronic structure of NO_2 . The agreement between this predicted structure and the experimental parameters was moderately good.

3.3 Magnetic Properties of Nitrogen Dioxide

NO_2 gas is paramagnetic, frozen N_2O_4 is diamagnetic. Paramagnetism gives nitrogen dioxide a volume susceptibility of $\chi = 3 \times 10^{-15}$ cgs units.

3.4 Electron Spin Resonance Spectra of Nitrogen Dioxide

Since NO_2 carries a free electron, it is paramagnetic and can be investigated by electron spin resonance (ESR) spectroscopy. It acts like a free radical. The ESR spectrum of liquid N_2O_4 at room temperature consists of a single, broad, unstructured band with a half-width of approximately 150 G and a g value of about 2.0. This has been attributed to NO_2 formed by the dissociation of N_2O_4 . The unpaired electron on NO_2 is most likely in an orbital of a_1 symmetry partially localized on the nitrogen atom. The ESR signal should be a triplet (due to the electron-nuclear-spin interaction). Failure to resolve this band at temperatures in the region of 273 K was attributed to a rapid rate of dimerization and dissociation, which is sufficient to broaden the lines beyond the point of resolution. The resolved spectrum of NO_2 molecules was obtained by trapping NO_2 radicals in various matrices, usually by irradiation of a matrix containing alkali metal nitrates. The resolved spectrum was shown to consist of an anisotropic triplet.

The ESR spectrum of dinitrogen tetroxide has been examined in the liquid and solid states between 77 and 300 K [31]. The nature of the equilibrium $2\text{NO}_2 \rightleftharpoons \text{N}_2\text{O}_4$ has been studied in the liquid state, and the concentrations of NO_2 have been determined by measuring the strength of the ESR signal. The equilibrium constant decreased from 43.54 ± 1.5 mol/L at 296 K to 0.11 ± 0.01 mol/L at 247 K, giving a heat of reaction of $\Delta H = 15.6 \pm 0.5$ kcal/mol for the dissociation. When the liquid was quenched to 77 K, an anisotropic set of triplets was observed with g values of g_x 2.0063, g_y 1.9960, g_z 2.0029, and g_{avg} 2.0018 and hyperfine-splitting constants (in G) of A_x 507, A_y 50.1, A_z 67.0, and A_{iso} 56.0. When the sample was warmed to 180 K, the triplets decreased in intensity and became isotropic with a splitting of 57 G. On recooling, the original anisotropic triplet was recovered.

3.5 Molecular Properties, Structure, Dipole Moment, Molecular Orbital Calculations of Nitrogen Dioxide

3.5.1 Molecular Properties and Structure of Nitrogen Dioxide

The reactivity of nitrogen dioxide and dinitrogen tetroxide is based on their molecular structure. The structure of nitrogen dioxide is unique in that it contains an odd number of electrons, 17 electrons, leaving an unpaired electron that seeks to pair itself. That can be done by pairing with itself in a labile bond forming dinitrogen tetroxide. Thus it both dimerizes and undergoes association reactions with other free radicals, adds to double bonds in unsaturated molecules, and takes part in hydrogen-abstraction reactions just as the methyl radical does. The molecular structure of nitrogen dioxide has been identified by spectroscopic investigations and by modeling its structure with computational chemistry.

The molecular structure of NO_2 is shown in Figure 6. The nitrogen dioxide molecule is in the shape of a triangle. The $\angle \text{O}-\text{N}-\text{O}$ bond angle between the two oxygen atoms is $134^\circ 4'$. The $\text{N}=\text{O}$ atom distance is $1.188 \pm 0.004 \text{ \AA}$. An exhaustive summary of the connections between the molecular structure of nitrogen dioxide and its reactivity with 441 references to the literature is given in [32] and [3]. The numerous reactions NO_2 can undergo are briefly summarized in Section 4.4.

Figure 6: Molecular structure of nitrogen dioxide

3.5.2 Molecular Orbital Calculations of Nitrogen Dioxide

A non-empirical self-consistent field method has been applied to the ground state and to a series of excited states of NO_2 to obtain potential-energy curves by varying the bond angle [33]. The resulting equilibrium bond angle for the ground state compared favorably with the experimental value. It was found that five transitions fall into the range covered by the long-wavelength spectrum, which explains the complexity of the spectrum. From the correlations between the electronic states of the bent molecule and those of the linear system, an attempt was made to obtain indications concerning the potential-energy surfaces of the $\text{NO} + \text{O}$ system as the NO_2 begins to dissociate. An attempt was made to explain the mechanism of the photolysis of NO_2 , and the anomalously long radiative lifetime of its first doublet excited state resulting from fluorescence decay. Oscillator strengths of the allowed and forbidden transitions in NO_2 were obtained [34]. The NO_2 excitation energies, potential energy surfaces, and os-

cillator strengths computed were then compared to experimental spectroscopic data, namely, absorption, fluorescence, chemiluminescence, predissociation, photolysis, and the absence of phosphorescence [35]. It was found that the main components of the visible spectrum are due to the transitions $2B1 \leftarrow 2A1$ and $2B2 \leftarrow 2A1$, with the $2B2$ state being responsible for the observed fluorescence emission, which has an anomalously long lifetime.

The electronic structures and spectra of nitrogen dioxide have been calculated by a semi-empirical method and the self-consistent molecular orbitals and energies of the π -electron system have been calculated [36]. However, for the non-bonding σ -electron system Hückel-type molecular orbitals were used. In nitrogen dioxide the totally symmetric combination of 2p oxygen orbitals and the sp^2 non-bonding nitrogen orbital mix strongly to form slightly bonding and slightly anti-bonding molecular orbitals. For nitrogen dioxide a series of transition energies was obtained, which may explain the experimental results. The complexity of the empirical data, however, precluded definite assignment of the observed band systems.

3.6 Solubility Properties of Nitrogen Dioxide

3.6.1 Solubility Properties of Nitrogen Dioxide in Other Liquids

The solubility of nitrogen dioxide in water is an important property because it is part of the industrial process in the production of nitric acid, it is important for the absorption of NO_2 in stack gases and pressurization gases vented from propellant tanks in water spray scrubbers, and it is the first step in a long chain of toxic reactions if NO_2 is accidentally inhaled by propellant-handling personnel. It is difficult to differentiate between the solubility of NO_2 and N_2O_4 because under most conditions at room temperature an equilibrium between the two exists in the solution as well as in the vapor space above the solution. The degree of dissociation of N_2O_4 in non-reactive solvents depends on the dielectric constants and polar properties of the solvents. The most important solution of NO_2/N_2O_4 equilibrium mixtures are those in concentrated nitric acid, commonly referred to as red fuming nitric acid (RFNA). Nitric acid and dinitrogen tetroxide are not completely miscible over the entire range of compositions. The phase behavior, miscibility limits, vapor pressure, and vapor composition of RFNA are discussed in *Encyclopedia of Oxidizers*, in the chapter "Red Fuming Nitric Acid."

NO_2 reacts immediately with H_2O upon dissolution, which prevents direct measurements on the physical phase equilibria of the chemical system. The reaction does not go to completion, and under certain conditions a two-phase system is formed [37]. Modeling this reacting system is a challenging task due to the complexities arising from the heterogeneous nature of the chemical reaction, the multiple components that are involved in the phase equilibria, ionic dissociation in water, self- and cross-associations among the molecules, and multiple chemical reactions that may occur before physicochemical equilibria is reached [38].

3.7 Thermodynamic Properties of Nitrogen Dioxide

3.7.1 Heat Capacity of Nitrogen Dioxide

The heat capacity of gaseous nitrogen dioxide at 298 K is $36.974 \text{ J mol}^{-1} \text{ K}^{-1}$. The heat capacity of gaseous nitrogen dioxide as a function of temperature can be calculated from the following polynomial equation:

$$C_p^\circ = A + B \times \tau + C \times \tau^2 + D \times \tau^3 + \frac{E}{\tau^2}$$

where C_p is the heat capacity in $\text{J mol}^{-1} \text{ K}^{-1}$, τ is the temperature in kelvin divided by 1000, and A, B, C, D, and E are constants listed in Table 1 for two different temperature ranges. Note that NO_2 is unstable at temperatures above 1000 K and the column for the higher temperature range 1200–6000 K is only of academic value.

Table 1: Thermodynamic property polynomial equation coefficients for gaseous nitrogen dioxide.

Temperature range, K	298–1200	1200–6000
A	16.10857	56.82541
B	75.89525	0.738053
C	−54.38740	−0.144721
D	14.30777	0.009777
E	0.239423	−5.459911
F	26.17464	2.846456
G	240.5386	290.5056
H	33.09502	33.09502

Data source: [39, 40]

3.7.2 Enthalpy of Formation of Nitrogen Dioxide

Table 2 is a summary of standard enthalpy of formation data assembled from various sources.

Table 2: Summary of literature data for standard enthalpy of formation (ΔH_f°) of gaseous nitrogen dioxide.

Enthalpy of formation		Author	Year	References
kJ/mol	kcal/mol			
+33.32	+7.964	Giauque and Kemp	1938	[41]
+33.095	+7.910 ± 0.2	JANAF	1971	[42]
+33.10	+7.911	NIST Chemistry WebBook	1964	[39]

Molecular mass 46.0055 g/mol

The differential enthalpy of formation of gaseous nitrogen dioxide as a function of temperature can be calculated from the following polynomial equation:

$$\Delta H = H^\circ - H^\circ_{298.15} = A \times \tau + \frac{B \times \tau^2}{2} + \frac{C \times \tau^3}{3} + \frac{D \times \tau^4}{4} - \frac{E}{\tau} + F - H$$

where ΔH is the enthalpy in kJ/mol, τ is the temperature in kelvin divided by 1000, and A, B, C, D, E, F, and H are constants listed in Table 1 for two different temperature ranges.

4 Chemical Properties of Nitrogen Dioxide

4.1 Thermal Decomposition of Nitrogen Dioxide

The thermal decomposition of nitrogen dioxide leads to nitric oxide and dioxygen in reversal of the formation of NO_2 from these gases at lower temperatures

The kinetics of the thermal decomposition of nitrogen dioxide were studied in a Vycor vessel over a temperature range of 630 to 1020 K for nitrogen dioxide concentrations from 10^{-8} to 10^7 molecule/cm³ [43, 44]. The reaction was found to be of second order with respect to nitrogen dioxide and to involve an activation energy of 112.5 kJ/mol (26.9 kcal/mol).

4.2 Photolysis of Nitrogen Dioxide

In the photolysis of NO_2 , using shorter and shorter wavelength light, the absorption of radiation and the formation of excited NO_2 molecules becomes noticeable at 6000 Å. This energy of excitation is not enough to dissociate the molecule, and it is either quenched or re-radiated as fluorescence. At shorter (4000 Å) wavelengths, the absorption becomes diffuse and fluorescence fades as dissociation begins:

Because of the competition from fluorescence and quenching the quantum yield is small. As the wavelength is further decreased and the energy of quanta increased, dissociation predominates. The intensity of fluorescence is zero by 3650 Å, absorption is continuous, and the quantum yield approaches 2. This leads to the second reaction:

and a total change of two molecules of NO_2 decomposed per quantum absorbed. Sharp absorption bands near 2596 Å support dissociation. The second diffuse region near

2459 Å corresponds to dissociation into nitric oxide and an excited oxygen atom:

Photolysis of NO_2 is of interest not only for atmospheric chemistry, but also for rocket propellant chemistry. If it is possible to isolate and stabilize some of the intermediate excited species, this might lead to more energetic oxidizers for rockets. Photolysis might also be a useful method of destroying NO_2 in waste gases.

Nitrogen dioxide photolysis has been studied by various investigators under different conditions, all at wavelengths between 3100 and 3700 Å [45, 46] and at 3660 and 4047 Å [47]. The proposed mechanisms differ in that one postulated that atomic oxygen attacks NO_2 in two ways, yielding NO and O_2 in one case and excited NO_3^* in the other. The excited NO_3^* can decompose to form atomic oxygen and NO_2 , it can be deactivated, or it can react with NO_2 . The second mechanism postulated a single mode of attack on NO_2 by atomic oxygen, again yielding excited NO_3^* . Of the two mechanisms, the first was rated as being more consistent with the thermal reactions of NO_2 and NO_3 . It is believed that both the linear and triangular forms of NO_3 play important roles in the photolysis of NO_2 .

The quantum yields of oxygen production in the photolysis of nitrogen dioxide have been determined at a series of wavelengths at room temperature and as a function of temperature at 3660, 4047, and 4358 Å [48, 49]. These values were satisfactorily correlated with the extent of dissociation into NO and O atoms by means of $^{18}\text{O}_2$ tracer techniques. A general mechanism was proposed for the photolysis of NO_2 from 3130 to 4047 Å. Temperature effects were correlated in terms of a theoretical calculation based on the population of the rotational energy levels of NO_2 . This led to a spectroscopic-photochemical determination of the dissociation energy of NO_2 that was in good agreement with one calculated from thermodynamic data.

Relative quantum yields for the photolysis of NO_2 to give NO have been measured at 5- or 10-nm intervals in the range of 295 to 445 nm and at several longer wavelengths [50]. The behavior of the quantum yield as a function of photon energy can be separated into three distinct wavelength regions: At all wavelengths shorter than 398 nm the quantum yield is almost constant and independent of NO_2 pressure in the range 0.5–4 mm Hg. The photodissociation probability of NO_2 remains close to unity for photolysis by all wavelengths shorter than the dissociation limit at 398 nm. At wavelengths longer than 430 nm, there is a small quantum yield for NO formation that decreases slowly with increasing wavelength. Quenching studies and variations in light intensity showed that these small yields are caused by the reaction of an electronically excited NO_2 molecule with ground state NO_2 . In the wavelength region between 400 and 430 nm, the quantum yield fell abruptly. Isotopic exchange experiments involving oxygen-18 confirmed that free oxygen atoms are produced in this region, even though the energy of the photolyzing quantum is less than the NO_2 dissociation energy.

The near-UV photodissociation of NO_2 has been investigated at excess energies from 600 up to 1700 cm^{-1} above the $\text{NO}_2 v = 1 + \text{O}^3\text{P}$ dissociation limit [51]. A complete

analysis of the $\text{NO}_x v=1$ fragment, including internal and translational energy as well as the angular properties of its vectorial parameters, was performed using resonance-enhanced multi-photon ionization with time-of-flight mass spectrometry. Two types of final state distributions of the fragments were found; the difference depending upon the excess energy with respect to the $\text{NO}_x v=1 + \text{O}^3\text{P}$ dissociation limit. Above the threshold, statistical rotational behavior with non-vanishing anisotropies was observed.

Velocity-map ion imaging has been applied to the photodissociation of NO_2 via the first absorption band at 308 nm using (2+1) resonance-enhanced multi-photon ionization detection of the atomic $\text{O}(^3\text{P}_j)$ products [52]. The resulting ion images were analyzed to obtain information about the speed distribution of the $\text{O}(^3\text{P}_j)$ products, the translational anisotropy, and the electronic angular momentum alignment.

Photochemical removal of NO_2 in N_2 or air (5–20% O_2) mixtures was studied using 172-nm Xe_2 excimer lamps at atmospheric pressure without using any catalysts [53]. When a high-power lamp (300 mW/cm^2) was used, the conversion of NO_2 (200–1000 ppm) to N_2 and O_2 in N_2 was >93% after 1 min of irradiation, whereas that to N_2O_5 , HNO_3 , N_2 , and O_2 in air (10% O_2) was 100% after 5 s of irradiation in a batch system. In a flow system, about 92% of NO_2 (200 ppm) in N_2 was converted to N_2 and O_2 , whereas NO_2 (200–400 ppm) in air (20% O_2) could be completely converted to N_2O_5 , HNO_3 , N_2 , and O_2 at a flow rate of 1 L/min. It was found that NO could also be decomposed to N_2 and O_2 under 172-nm irradiation, though the removal rate was slower than that of NO_2 by a factor of 3.8.

4.3 Radiolysis of Nitrogen Dioxide

Radiolysis of nitrogen dioxide would occur in the upper strata of the stratosphere where cosmic radiation both ionizes the oxygen and ozone and initiates the reaction of oxygen atoms and nitrogen atoms, but also destroys the nitrogen dioxide thus formed. The radiolysis of liquid N_2O_4 is discussed in *Encyclopedia of Oxidizers*, “Dinitrogen Tetroxide.”

4.4 Reactions of Nitrogen Dioxide

The nitrogen dioxide equilibrium mixture is extremely reactive, entering into chemical reactions with inorganic as well as organic reaction partners. In interpreting a particular reaction, the first problem is to determine whether the free radical NO_2 or its dimer molecular N_2O_4 or the ionic nitrosyl nitrate form of N_2O_4 is the reacting species. Thus in gas-phase reactions at high temperature, NO_2 monomer greatly outweighs the N_2O_4 dimer, while in the liquid state the opposite is true. A good overview over reactions of NO_2 and N_2O_4 and the connections between the molecular

structure of nitrogen dioxide and its reactivity is given in two historic reviews by Gray and Yoffe [3, 32].

In our book, we are mostly interested in the reactions of NO_2 that lead to hypergolic ignition with reactive fuels. These hypergolic ignition reactions will be discussed in a future volume of this series in the *Encyclopedia of Rocket Propellants*.

4.4.1 Reactions of Nitrogen Dioxide with Inorganic Compounds

4.4.1.1 Reactions of Nitrogen Dioxide with Hydrogen

While a combination of nitrogen dioxide with hydrogen could theoretically be used as a rocket propellant, the disparate boiling points of the two liquids would make a practical design very difficult. The reaction of nitrogen dioxide with hydrogen has been examined mostly as part of kinetic and ignition studies. The combination is not hypergolic.

4.4.1.2 Reactions of Nitrogen Dioxide with Water

The most important reaction of NO_2 with any other inorganic chemical is the reaction with water. The reactions of nitrogen dioxide are a complex pattern of its free radical and non-radical modes of reaction.

One of the most important reactions involving nitrogen dioxide is the absorption in water and the reaction with water, leading to the formation of nitric acid in large-scale industrial nitric acid production plants [54, 55]. The NO_2 gas dissolves in water physically before it reacts chemically. Not all dissolved NO_2 will react, and some remains as a physical solution in the resulting nitrous acid/nitric acid/water mixture [56]. This reaction also takes place on a global scale in the atmosphere of our planet Earth. The nitrogen dioxide in the atmosphere will form by lightning or as a result of combustion processes, both natural combustion like forest fires and industrial, residential, and automotive emissions. The absorption in and reaction with water is an important step in scrubbers for the removal of NO_2 from pressurant gases vented from dinitrogen tetroxide tanks at rocket test sites and in reusable spacecraft that have been returned from space.

Studies of the gas-phase reaction of water vapor and ppm concentrations of nitrogen dioxide were made at atmospheric pressure and near ambient temperatures [57]. The initial rate of disappearance of nitrogen dioxide was first order with respect to water and second order with respect to nitrogen dioxide. Nitric oxide and nitric acid were the principal products. A third-order rate constant of $(5.50 \pm 0.29) \times 10^4 \text{ L}^2 \text{ mol}^{-2} \text{ s}^{-1}$ was found at 25°C . These results are applicable to air pollution studies but also for NO_x scrubbers based on the absorption of nitrogen dioxide into aqueous solutions.

The heterogeneous reaction of NO_2 with water has been known for decades to generate HONO, a major source of $\cdot\text{OH}$ that drives the formation of ozone and other air pollutants in urban areas. The reaction is first order in NO_2 and in water vapor, and the formation of a complex between NO_2 and water at the air-water interface has been

hypothesized as being the key step in the mechanism. Long-optical-path-length FTIR studies of the loss of gaseous NO_2 and the formation of the products HONO, NO, and N_2O were carried out to measure species generated on the surface during the reaction, including HNO_3 , N_2O_4 , and NO_2^+ [58]. A reaction mechanism was proposed that hypothesized that the symmetric form of the NO_2 dimer, N_2O_4 , is taken up on the surface and isomerizes to the asymmetric form, ONONO_2 . The latter autoionizes to $\text{NO}^+ \text{NO}_3^-$, and it is this intermediate that reacts with water to generate HONO and surface-adsorbed HNO_3 . Nitric oxide is then generated by secondary reactions of HONO on the highly acidic surface.

4.4.2 Reactions of Nitrogen Dioxide with Organic Compounds

The abstraction of hydrogen atoms from alkanes is a characteristic reaction of free radicals, which is how nitrogen dioxide reacts with alkanes:

This initial step is succeeded by rapid secondary reactions of the alkyl radical and oxidation. Prominent among these competing reactions are nitration by radical-radical association:

NO_2 reacts readily with unsaturated organic compounds. The primary products of the addition of NO_2 to olefins are α,β -dinitro-compounds and α -nitro- β -nitrites, often in nearly equal proportions. It is the reactivity of NO_2 and N_2O_4 with organic compounds, which severely limits the choice of polymeric materials for gaskets and propellant expulsion bladders and diaphragms in propellant tanks.

For additional information about reactions of NO_2 and N_2O_4 with organic compounds, we refer readers to other publications in the literature [59]. Other reactions are summarized in conference proceedings about nitration methods [60].

4.5 Analysis of Nitrogen Dioxide

Analytical methods for determination of nitrogen dioxide in the air would be of importance for monitoring workplaces at rocket test and launch facilities where personnel work in proximity to oxidizer run tanks, tank trucks, and storage areas. Such analytical methods are also widely used for monitoring atmospheric air pollution in urban areas.

In the case of accidental releases of dinitrogen tetroxide into the atmosphere, the initial release may be in the form of N_2O_4 , but as soon as the liquid evaporates and the vapor cloud is diluted as it diffuses into ambient air, most of it will convert to NO_2 .

Therefore, analysis methods are only calibrated for NO_2 and not for N_2O_4 , which may accompany the NO_2 but only in small concentrations.

This section overlaps with and partially duplicates a similar section on the analysis of nitrogen oxides in the chapter on N_2O_4 . That section deals mostly with the analysis of liquid N_2O_4 but includes some information on the analysis of NO_2 in the gas phase.

4.5.1 Analysis of Nitrogen Dioxide in Air at Rocket Test Facilities

This section on the analysis of NO_2 in air overlaps with a similar or nearly identical section for the analysis of N_2O_4 in the air of work spaces.

A portable monitor for recording NO_2 concentrations in workroom air and stack gases allowed the gas sample to flow concurrently with the reagent, N-1naphthylethylenediamine dihydrochloride, through a beaded column [61]. Diazotization of the reagent produced a colored solution that was measured by a flow-through colorimeter. Concentrations ranging from 0.5 to 15000 ppm could be measured.

The best wavelength for detection of red NO_2 gas in air is 400 nm. For continuous spectrophotometric analysis of NO_2 in air by drawing sample air through a 10-cm UV-vis spectrophotometer cell, a correction needs to be applied for invisible N_2O_4 based on the known dissociation curve, and the accuracy is $\pm 2.5\%$ relative for NO_2 concentrations up to 4 vol.-% [62].

For occasional spot checks of NO_2 concentrations in air at the workplace, the easiest method is with gas detection tubes made from glass tubes that contain an indicator supported on a granular material, which changes color when exposed to NO_2 . Such tubes are available from Dräger, MSA, “Kitagawa,” and others. Gas detection tubes are sensitive to as little as 0.5 ppm NO_2 and can measure up to 100 ppm NO_2 with 10 strokes of a manually operated bellows pump. Dräger NO_2 gas detection tubes are available for two ranges of concentrations (Table 3).

Table 3: Dräger nitrogen dioxide gas detection tubes and CHIP boards.

Type	Tube designation	Concentration range	Dräger part number
Glass tube	Nitrogen Dioxide 0.5/c	0.5–25 ppm	CH 30 001
Glass tube	Nitrogen Dioxide 2/c	2–100 ppm	67 19 101
CHIP 10-capillary board	Nitrogen Dioxide	0.5–25 ppm	64 06 120

Data source: https://www.draeger.com/en-us_us/Products/Sampling-Tubes-and-Systems; accessed 17-Oct-2021

The Dräger CHIP is a self-contained unit that has a pump and a digital readout. Each disposable chip board contains 10 measurement capillaries filled with a substance-

specific reagent system. The reactive preparations necessary for detection are kept in hermetically sealed glass capillaries until needed. When the chip is inserted into the analyzer, all information required for detection is transferred to the analyzer by means of a bar code:

- type of gas,
- measuring range,
- measuring time,
- parameters for the calibration function,
- required flow rate

The analyzer records the measurement effect optoelectronically, thereby eliminating human error in reading a color scale. In the CHIP measuring system, miniaturization has resulted in a reduction in the sample volume necessary for a measurement (compared to the manual bellows pump with 10 strokes). For a typical measurement, only 30 mL of air is needed for a measuring time of approximately 2 min and a flow of 15 mL/min. The power needed for operation of the analyzer is provided by four AA batteries. After inserting the chip, an optical system calculates the number of remaining measurements still available on the chip being used and displays this together with the gas type and the measuring range. Up to 50 measurement results can be stored in the machine with the name of the measured substance, the concentration, date and time of the measurement, and a code letter to help identify the measurement location. Newer equipment is available with analyzers in the Pac[®], X-dock[®], and X-am[®] series.

The popular Dräger tube for NO₂ was tested again for accuracy with NO₂ vapors from a vapor generator that was calibrated with the Saltzman reagent method on air samples drawn through an impinger with NaOH [63]. These tubes change color from white to blue gray based on the reaction of NO₂ with diphenylbenzidine. This indication is affected by free halogens. The end point on the NO₂ tubes was difficult to read, but all results for NO₂ tubes were on the unsafe side (low readings). At 6.3 ppm NO₂ the deviations from the true, analyzed concentration were -13 and -28%. This deviation may have been corrected in the meantime.

A method for determining 2 to 10 ppm of NO₂ in air, a liquid absorption method, is based on a Griess-Ilosvay reaction in which nitrogen dioxide recovery can be improved by the incorporation of sodium arsenite in an alkaline absorption solution [64]. The same author also described a cheap test-paper method unaffected by humidity and air that involved the use of papers treated with p-anisidine and glycerol, with a storage life of 3 months.

As part of an effort to upgrade the sensor technology background information, NASA requested information from a total of 27 manufacturers of portable multi-gas instruments [65]. A set of criteria was established to determine which vendors would be selected for laboratory evaluation. Each of the 27 manufacturers of multi-gas analyzers was sent a copy of the criteria and asked to fill in the appropriate information pertaining to their instrumentation. Based on the results of the sensor criteria work-

sheets, a total of 9 vendors out of 27 surveyed manufacturers were chosen for evaluation. Each vendor included in the final evaluation process was requested to configure each of two analyzers with NO₂, NH₃, O₂, and combustible sensors.

Recording and monitoring instruments need to be calibrated from time to time with NO₂/air mixtures with exactly known NO₂ concentrations. Considering the high reactivity of NO₂, it is not possible to keep NO₂/air calibration mixtures in compressed gas cylinders for longer times. Fresh NO₂/air mixtures with accurate and reproducible NO₂ concentrations can be generated by permeation tubes. NO₂ gas mixtures in the range of 5 to 15 μmol/mol with a standard relative uncertainty of 0.4% can be produced with permeation tubes. Nitric acid contamination present in the gas mixtures was determined using a FTIR spectrometer and a non-dispersive UV analyzer and subtracted from the NO₂ readings [66].

Numerous electrochemical semiconductor sensors that have been calibrated for NO₂ and other atmospheric contaminants are based on tin(IV) oxide.

One of the main applications of conducting polymers in chemiresistor sensors for sensing hazardous hypergolic liquid propellant vapors at explosive, toxic, and threshold limit value concentration levels is for vapors of NO₂ and MON-3 [67]. The same instruments can also detect vapors of hydrazines, such as hydrazine, methylhydrazine (MMH), and unsymmetrical dimethylhydrazine (UDMH) and HCl, in the exhaust plumes of solid propellant rockets. To properly use these instruments, one must understand electrical conducting mechanisms during sensing, thickness of sensing layer, factors that influence conductivity, response time, recovery time, detectable range, interference from other pollutants, and minimum detectable limit of the sensors. Advantages and disadvantages of conducting polymer coated fabrics as novel chemiresistor sensors over inorganic substrates need to be evaluated.

Both badge- and tube-type passive samplers can be used to monitor NO_x pollution in areas where expensive electronic equipment is not available. Passive samplers are less reliable, and results may vary with how they are applied under field conditions [68].

The methods summarized in this chapter are subdivided into those that analyze nitrogen oxides in air directly and those that absorb oxides first into water or another solvent for subsequent analysis by a wet chemical method. The development of NO₂ detectors went on hand in hand with the development of analytical instruments for the detection of other hazardous substances in air [69]. Hundreds of instruments are available commercially for the analysis of NO_x in polluted urban atmospheres, in stack gases of stationary power plants, and in automobile exhaust. Many of those can be used at rocket test sites as well.

4.5.2 Direct Reading Instruments for Analysis of Nitrogen Dioxide in Air at Workplace

At the beginning of the Space Shuttle era, an NO₂ analyzer was developed specifically for use in the fueling of the Shuttle Orbital Maneuvering System (OMS) and Attitude Control System (ACS) tanks with MON [70]. The instrument was developed for NASA by what was then Energetics Science, Inc. The instrument consisted of a sample pump, an electrochemical cell, and control and display electronics. The pump pushed the air sample through an electrochemical cell where the vapors were analyzed, and an output proportional to the NO₂ concentration was produced. The output was displayed on a panel meter and also available at a recorder jack for a permanent record and monitoring with a threshold alarm. The electrochemical cell contained platinum electrodes, and the sensing and counter electrodes were potentiostatically controlled at -200 mV with respect to the reference electrode. The cell was filled with electrolyte, consisting of 13.5 cm³ of a 23% solution of KOH (which would of course change with time due to absorption of atmospheric CO₂). The range was 0.1–10 ppm, and the 90% response time was 20 s.

4.5.3 Analysis of Nitrogen Dioxide in Air with Absorption into Water

Instruments that first absorb NO₂ into water or a mildly caustic solution rely on the initial conversion of NO₂ into nitrate and nitrite in aqueous solution:

As the next step, it is much easier to analyze for nitrite than it would be to analyze for nitrate. Nitrite in aqueous solution is typically analyzed by the Saltzman reagent (also called Lunge's Reagent, Griess-Ilosvay Diazo reagent) which forms an intensely red colored diazo dye with traces of nitrite [71]. Chlorine, sulfur dioxide, nitrosyl chloride, ozone, and reducing agents would interfere in this reaction. These wet methods are more time consuming than modern instrumentations that give direct readings and are now only used as referee methods to verify proper operation of some of the direct-reading instruments in use.

A crude indication of the presence of NO₂ (or other oxidizing gases) in air can also be achieved by moist potassium iodide-starch paper, which turns purple-brown as the result of the oxidation of iodide by NO₂. Chlorine, sulfur dioxide, ozone, and any other oxidizing gas will interfere. See also [72].

A spectrophotometric method determined the NO₂ content by absorption at 400 nm in a cell with a 10-cm optical path and applied a correction factor for undissociated (invisible) N₂O₄. The accuracy was ±3.5% relative for concentrations up to 4 vol.-% NO₂ [73].

The spectrophotometric Saltzman (Griess-Ilosvay) reagent wet method is more accurate, less susceptible to interference, and faster to perform than the phenyldisulfonic acid method, which was once recommended as an ASTM procedure [74, 75]. Both methods depend on the complete conversion of all NO in the sample using oxygen instead of air to achieve complete conversion to NO₂, which is a very slow process. Depending on the initial NO concentration and O₂ partial pressure, the complete conversion can take from several hours up to a day.

A comparison of wet chemical spectrophotometric methods for the analysis of nitrogen dioxide in fumes from explosives showed that results obtained with three different methods agreed with each other, but that some reagents required excessively long contact times for complete absorption of NO₂ (on the order of 12h overnight). Much faster absorption, by shaking a gas sample with liquid for only 3 min, was possible with a dilute NaOH solution, achieving 92% of the completeness of an overnight contact time with the acidic reagent in direct contact with the gas [76].

A method for determining 2 to 10 ppm of NO₂ in air is a liquid absorption method based on a Griess-Ilosvay reaction in which nitrogen dioxide recovery can be improved by the incorporation of sodium arsenite in an alkaline absorption solution [64]. The same author also described a cheap test-paper method that was unaffected by humidity and air and involved the use of papers treated with p-anisidine and glycerol, with a storage life of 3 months.

The sodium arsenite method has a constant-high collection efficiency (82%) for nitrogen dioxide and is insensitive to normal variations in operating parameters [77]. Nitric oxide and carbon dioxide are positive and negative interferents, respectively.

4.5.4 Dosimeters for Cumulative Analysis of Nitrogen Dioxide in Air

Gas detection tubes containing an indicator on a solid sorbent (silica gel) that changes color irreversibly are very popular for a quick but less accurate, semi-quantitative indication of nitrogen oxides in air, requiring active pumping either by hand with a bellows pump counting the number of strokes or using a mechanical pump with calibrated air flow rates. Common brands include Dräger, MSA, and Kitagawa.

Thin-film personal dosimeters patterned after those used for ionizing radiation can be used to monitor the cumulative exposure of rocket test stand personnel to toxic vapors [78, 79]. They are often worn as badges on work clothing, on a lapel button close to the nose.

A simple personal dosimeter for NO₂ can be prepared by dipping discs cut from a silica gel chromatogram sheet into a solution of diphenylamine and oxalic acid in methanol and drying them in air [80]. The strips suffer from exposure to heat and/or light and should be covered by a perforated plate in a lapel-mounted plastic holder. Nitrogen dioxide forms a green color while other oxidizers form a blue color. The impregnated disc is mounted on a color standard for concentration-time products of 50, 100, and 300 ppm-minutes.

A cumulative air sampling method for the collection of air samples containing both NO₂ and NO in the range of 0.5 to 5 ppm NO₂ and 9 to 50 ppm NO is based on trapping the two gases in a solid sorbent sampling tube by collecting NO₂ on a triethanolamine (TEA)-impregnated molecular sieve surface [81]. Nitric oxide is oxidized to NO₂ by a solid oxidizer and the converted NO collected on another section of TEA sorbent. The trapped NO/NO₂ on each TEA section is desorbed and the concentrations are determined spectrophotometrically. At all concentrations tested, the collection efficiency for NO₂ averaged approximately 96%. The collection efficiencies for NO were as follows: at 9 ppm, 97%; at 11 ppm, 106%; at 24 ppm, 84%; and at 50 ppm, 67%.

4.5.5 Continuously Reading Direct Readout Monitors of Nitrogen Dioxide in Air

There is a large number of air monitoring instruments on the market, some of which are specific to nitrogen dioxide, while others can detect more than one propellant contaminant at a time, e.g., hydrazine or MMH. The problem with procuring one of those instruments is that this is a very limited market, and companies enter and leave the market at a high rate. Other companies are bought out or merge and change their names. Instruments may not be supported with spare parts for more than a few years. An evaluation of commercially available portable nitrogen dioxide detectors done in 1990 may be without value 10 years later and would have to be redone every few years [82].

Under contract to USAF Edwards Air Force Base, Mine Safety Appliances Company once developed an instrument suitable for continuous monitoring of toxic levels of NO₂, UDMH, B₅H₉, N₂H₄, F₂, and ClF₃, but this is no longer in use [83].

4.5.5.1 Infrared Absorption NO₂ Monitors

Nitrogen dioxide in air can be detected by its IR absorption spectrum. Instruments based on the IR absorption of NO₂ can measure the toxic gas concentration, record the variation during a full work shift to document compliance with workplace safety regulations, and sound an alarm if the tolerable concentration is exceeded. The threshold where the alarm starts ringing would be set close to the Threshold Limit Value – Time Weighted Average (TLV-TWA) established by the occupational health agencies [84].

4.5.5.2 Wet Chemistry Spectrophotometric NO₂ Monitors

For this continuous analysis method, the gas stream to be analyzed is aspirated into a capillary glass spiral column where it flows concurrent or countercurrent to a stream of absorbent solution, which may or may not already have the color-forming reagent in it [85]. The most commonly used reagent for NO₂ analysis in these instruments is the Griess-Saltzman reagent [86, 87]. The detection limit is about 1×10^{-10} by volume for 1-h measuring periods. The question was which calibration method should be preferred, feeding a known NO₂ concentration in a gas stream from a permeation device into

the instrument or using a standardized sodium nitrite solution to replace the effluent from the absorption loop [88]. Permeation tubes were used to prepare standard atmospheres at realistic levels, 0.02 to 1.8 ppm of NO_2 . It was shown that 1 mol of nitrogen dioxide is equivalent to 0.764 mol of nitrite ion with use of the unmodified Saltzman reagent. Two absorbers provide separate analyses, one for NO_2 alone and one for the sum of NO and NO_2 after oxidizing the sample stream with ozone or chlorine dioxide, followed by a wet Griess-Saltzman reagent online analyzer [89].

4.5.5.3 Fiber-Optic NO_2 Monitors

A fiber-optic chemical dosimeter system was patented that can detect the presence of nitrogen dioxide using colorimetric sensors that react selectively with the NO_2 and then absorb laser light pulses communicating through a fiber-optic network having a diode laser source transmitting interrogation pulses to a multi-station array of distributed sensors covering a wide area propellant storage or rocket launch site, the sensor being reactive cladding or distal end types, both providing optical reflective returns transmitted to an optical reflectometry monitor to determine the concentration and location of gas clouds over the monitored area [90]. For example, phosphomolybdic acid reagent in the reduced (blue) state can be coated at the end of a fiber optic for reacting to the presence of nitrogen dioxide and changing color. The same apparatus can also be used for detecting hydrazine vapors, starting with phosphomolybdic acid reagent in the yellow state, changing color to blue in the presence of hydrazine.

A fiber-optic NO_2 and hydrazine sensor used an acid-base indicator that underwent color changes depending on which gas was present [91, 92]. Bromothymol blue bromocresol green mixture (1/1) in hydrogel (1/1) produced a blue-green indicator for hydrazine and/or NO_2 . The sensor was tested several times over a period of 8 weeks, and the response was consistent when exposed to 52 and 18 ppm hydrazine or 400 and 200 ppm NO_2 .

4.5.5.4 Thin-Film Sensors

Chemiresistors change their electric conductivity in the presence of certain chemicals. A review article covered the main applications of conducting polymers in chemiresistor sensors for sensing hypergolic liquid propellant vapors and toxic exhaust plume acidic vapors of solid rocket motors at threshold limit value concentration levels [67]. This review included NO_2 and MON-3. The discussion of key features of sensors, such as conducting mechanisms during sensing, thickness of sensing layer, factors that influence conductivity, response time, recovery time, detectable range, and minimum detectable limit, is a good introduction to this topic.

4.5.6 Leak Detection Instruments

In addition to active leak detectors that sound an alarm if a leak is detected, passive leak detectors will not only alert the observer, but also locate the leak.

4.5.7 Remote Sensing of Nitrogen Dioxide for Atmospheric Air Pollution Studies

The concentration of NO_2 in Earth's atmosphere has been determined in real time and with a sensitivity of 1 ppm by laser excitation at 4416 and 4880 Å and fluorescence at 0.7 to 0.8 μm [93]. The method was tested on typical smoggy days in the Los Angeles area.

Using a pulsed dye laser and a non-resonant optoacoustic detector, the absorption spectrum of NO_2 has been measured in the spectral region of 480–625 nm at various cell pressures and at various concentrations in air [94]. The results of the measurements as a function of NO_2 concentration in air demonstrated the detection sensitivity of the system. An extrapolated sensitivity of 4 ppb NO_2 /W of laser power was achieved. Similar equipment can be used to remotely monitor N_2O_4 storage areas for potential leaks.

5 Toxicity of Nitrogen Dioxide

Most toxicity studies are related to the inhalation of NO_2 from atmospheric pollution, often in combination with other air pollutants. Other studies are concerned with the formation of NO_2 during the combustion of propellants in guns and detonation of explosives in military ordnance in battlefield situations.

The hazard index, the vapor pressure divided by the toxicity number, of nitrogen dioxide and dinitrogen tetroxide is the highest among all currently used rocket propellants. There have been dozens of industrial and agricultural worker fatalities due to nitrogen dioxide poisoning, although few of them were caused by the use of N_2O_4 as a rocket propellant. Although the previous sections in this book dealt mostly with N_2O_4 , the inhalation toxicity studies are done almost exclusively only with the dissociation product of N_2O_4 , NO_2 vapor, at low concentrations. In most cases the leakage and spill accidents we are concerned with will involve the equilibrium mixture of dinitrogen tetroxide and nitrogen dioxide at the natural boiling point, just above room temperature. The small percentage of N_2O_4 present in the vapor has been neglected by most investigators. The contribution of N_2O_4 to NO_2 toxicity is unknown. In most cases, either of the two nitrogen oxides reacts quickly with water in body fluids to form nitric acid and nitrous acid. There are many summary publications on the toxicity of nitrogen oxides, mostly relating to the occurrence of nitrogen oxides in smog in polluted urban and industrial atmospheres. Relatively few experiments, many of those sponsored by rocket-propellant-using agencies, have used pure nitrogen dioxide for animal exposure tests and the establishment of the safe tolerable limits of this pollutant.

The most comprehensive and authoritative publication on the health effects of nitrogen oxides is the summary compiled by the World Health Organization (WHO) Task Group on Environmental Health Criteria for Nitrogen Oxides, which is updated periodically [95]. Other useful summaries are [96, 97]. The effects of exposure to high-

level NO_2 are of great interest to the military since high levels of NO_2 may be found in combat situations in the combustion products of propellants and explosives [98, 99]. It is also important to the civilian sector in occupational settings where accidents may occur, such as in silo filler accidents on agricultural farms. More information is needed on the chemistry of NO_2 interaction with body tissues, on the dosimetry of its uptake (isolated lung), on the biological effects of exposure *in vivo* in small animals (rats), large animals (sheep), and, finally, in the most relevant species, humans [100]. Most of these published studies are concerned with the lifelong, low-level inhalation of NO_x by the general population at large and not so much with the exceedingly rare accidental exposure of military personnel and rocket launch site or missile silo propellant-handling personnel to high levels of NO_2 [101]. Based on epidemiological studies, clean air legislation limiting the amount of allowable NO_x in the air in population centers can have a significant impact on economics and energy use patterns, both for stationary power plants and mobile power plants in automobiles and airplanes. Overly restrictive air pollution regulations, such as in California, may cause some industrial activities to leave the state and relocate to areas with less restrictive air pollution regulations, such as south of the border.

5.1 Inhalation Toxicity of Nitrogen Dioxide and Dinitrogen Tetroxide

Since the first documented fatal poisoning caused by NO_2 in 1804, several hundred more accidental poisoning deaths due to NO_2 have occurred worldwide [102].

Because of the relatively low water solubility of NO_2 and N_2O_4 , it is only slightly irritating to the mucous membranes of the upper respiratory tract. Therefore, at low concentrations where the red color of fumes is not visible, the warning power of NO_2 and N_2O_4 is low, and dangerous amounts of the vapor may be inhaled before the worker notices any real discomfort. The odor threshold is often assumed to be 0.2 ppm. Higher concentrations (60 to 150 ppm) cause immediate irritation of the nose and throat with coughing and burning in the throat and chest. Symptoms often clear after breathing fresh air, and the worker may feel well for several hours. After a relatively symptom-free 5- to 72-h period, pulmonary edema gradually develops, causing fatigue, restlessness, coughing, difficulty in breathing, frothy expectoration, mental confusion, lethargy, cyanosis, and a weak, rapid pulse. Inflammation of the lungs causes exudation into alveolar spaces interfering with gas exchange in lungs. The fluid lost from the blood also results in severe hemoconcentration. Unconsciousness and death by asphyxiation can result, usually within a few hours following the onset of pulmonary edema. Some patients who recover from the acute effects later may develop chronic pulmonary disease. The minimum lethal and maximum tolerated (survivable) human exposures (time $\times$ concentration product) to NO_2 and N_2O_4 have not been exactly established. Concentrations of 100 to 150 ppm are dangerous to humans for short exposures of 30 to 60 min. Concentrations of 200 to 700 ppm may be fatal after even very

short exposures. Data collected in a 1976 literature review by ACGIH suggest that a 60-min exposure of humans to 100 ppm leads to pulmonary edema and death, 50 ppm leads to pulmonary edema with possible subacute or chronic lesions in the lungs, and 25 ppm leads to respiratory irritation and chest pain.

Inhalation of brown fumes from the evaporation of N_2O_4 is a serious health threat and must be avoided. The exact composition of the brown fumes varies, but one cannot differentiate between the toxic effects of undissociated, colorless N_2O_4 and its dissociation product, the distinctly colored red-brown NO_2 . The red color of NO_2 becomes visible only in warm air at temperatures above 293 K (20 °C). There may be an invisible N_2O_4 toxicity hazard at lower temperatures.

The distinct odor threshold for NO_2 is at 10 ppm by volume. Larger concentrations can be recognized by their intense red-brown color and their tendency to linger along the ground since the vapors are heavier than air. The density of NO_2 at 294 K (21 °C) is 3.3 g/L, so it is about three times heavier than air. Nitrogen dioxide clouds are observed not only where N_2O_4 is used as a rocket propellant, but also when the gas space above red fuming nitric acid (RFNA) is vented or during the startup or shutdown of rocket engines operating with nitric acid as the oxidizer.

Inhalation of nitrogen dioxide in high concentrations may result in acute bronchospasm, delayed pulmonary edema, and late *bronchiolitis obliterans*, in that sequence. Low concentrations induce pulmonary fibrosis with chronic exposure [103]. See also [104–107].

NO_2 is a free radical and powerful oxidant that is reduced to nitrite ion NO_2^- in the lung; NO_2^- is then oxidized to nitrate ion NO_3^- in the blood. NO_2 in the presence of O_3 in a polluted atmosphere produces N_2O_5 and NO_3 (a free radical), both of which are more toxic than NO_2 . A potentiating effect that is observed in the toxicity of NO_2 plus O_3 (compared to effects of NO_2 or O_3 alone) may be explained on the basis of N_2O_5 and NO_3 formation [108].

The vapors escaping from RFNA at room temperature are essentially N_2O_4 and NO_2 , and the inhalation toxicity is the same as that of N_2O_4 without any nitric acid present [109].

To investigate the effects of anisodaminum and dexamethasone on the changes of blood gas of N_2O_4 -poisoned test animals, 224 male Wistar rats were divided randomly into four groups: **(1)** N_2O_4 blast-poisoned combined injury group; **(2)** anisodaminum-treated group; anisodaminum (3 mg/kg) was given *ip* immediately, 15 min, and 2 h after the injury; **(3)** dexamethasone-treated group; dexamethasone (10 mg/kg) was given *ip* immediately, 15 min, and 2 h after the injury; **(4)** anisodaminum and dexamethasone combination-treated group; anisodaminum (3 mg/kg) and dexamethasone (10 mg/kg) were given *ip* immediately, 15 min, and 2 h after the injury. Each group was subdivided into a control group and six treatment groups, which were necropsied 3, 6, 12, 24, 48, or 72 h after the injury for blood gas analysis. Measurements showed that in the N_2O_4 blast-poisoned group, PaO_2 and pH of the plasma were significantly decreased, while PaCO_2 was increased. The combined use of anisodaminum and dexamethasone in the

early stage significantly ameliorated the disorders of the blood gas of the injury. It was suggested that the combined use of anisodaminum and dexamethasone in the early stage is effective in the treatment of blast injury caused by explosion of dinitrogen tetroxide [110].

The PaO_2 of rats in three groups, especially that of the blast-poisoned group, was significantly decreased 3–6 h after the injury, and several died from respiratory failure. Each group underwent pathomorphologic changes in the main organs, and the change in the blast-poisoned group was the worst [111].

5.1.1 Chronic Exposure to Nitrogen Dioxide

Chronic exposure to nitrogen dioxide is usually associated with atmospheric pollution and urban smog. It is less likely to occur at rocket test sites or rocket launch sites [112]. Lung damage can be caused by long-term exposure to as little as 2 ppm [113]. Rats exposed continuously to 2 ppm NO_2 in air survived their ordinary lifetimes with persistent tachypnoea and usually died of non-pulmonary diseases, but they showed a reduced cleansing function of the periphery of the lung.

5.1.2 Olfactory Threshold

It is strange that for a common chemical that is so widely used whose toxicity has been thoroughly examined it is difficult to find reliable data on the olfactory threshold for this toxic compound. The odor threshold was once assumed to be 0.2 ppm. The distinct odor threshold for NO_2 is 10 ppm by volume. In a human volunteer test, one-fourth of the subjects ($N = 59$) tested could detect NO_2 at 0.9 ppm. With 1 ppm NO_2 , 8 of 59 (13.6%) subjects experienced irritation of the nasal mucosa [114]. It would be important to know whether the olfactory threshold at which NO_2 vapors can be reliably identified by their odor is above or below the Immediately Dangerous to Life or Health (IDLH) concentration of 20 ppm. Also, at what concentration do NO_2 vapors become visible in air near a leak? N_2O_4 vapors are invisible but just as toxic as visible NO_2 vapors.

The odor threshold levels for NO_2 have been generally quoted at 5 ppm by volume. Seven years of field experience by propellant loading personnel have indicated that the actual odor thresholds are considerably below these literature values [115]. Since odor threshold levels are used by safety and operating personnel at Kennedy Space Center as an indication of exposure, it was considered appropriate to evaluate this field experience. On the basis of these data and the results of some controlled studies, it was concluded that the actual odor thresholds are 0.5 ppm or less for NO_2 .

5.2 Maximum Allowable Workplace Concentrations for Nitrogen Dioxide

The maximum allowable workplace concentration as established by the US Occupational Safety and Health Administration has remained constant for a relatively long time, compared to the several-orders-of-magnitude changes that occurred during the same time for hypergolic hydrazine-based fuels. The American Conference of Governmental Industrial Hygienists (ACGIH)-recommended maximum allowable concentration, time-weighted average TWA for an 8-h workday at one time was 5 ppm until 1990, when it was lowered to 3 ppm. The current guidelines for limits on exposure to $\text{NO}_2/\text{N}_2\text{O}_4$ vapors are listed in Table 4.

Table 4: Maximum exposure limit guidelines for nitrogen dioxide

ACGIH TLV	OSHA PEL	NIOSH IDLH	NIOSH REL
STEL: 5 ppm; TWA: 3 ppm	(vacated) STEL: 1 ppm (1.8 mg/m ³) Ceiling: 5 ppm (9 mg/m ³) PEL: Ceiling 5 ppm	IDLH: 20 ppm; STEL: 1 ppm; STEL: 1.8 mg/m ³	ST: 1 ppm

STEL Short-term exposure limit

PEL Permissible exposure limit

OSHA Occupational Safety and Health Administration

NIOSH National Institute for Occupational Safety and Health

REL Recommended exposure limit

The same exposure guidelines would apply to military and space agency personnel, although the likelihood of accidental exposure to high concentrations of NO_2 is much higher for those groups than for the population at large [116].

The National Ambient Air Quality Standard (NAAQS) for NO_2 , initially established in 1971, is 0.053 ppm (annual average). Ambient concentrations monitored in urban areas in the United States are approximately 0.015 ppm, as an annual mean, i.e., below the current NAAQS. Short-term (1-h peak) NO_2 concentrations outdoors are not likely to exceed 0.2 ppm, and even 1-h periods exceeding 0.1 ppm are infrequent. Inside homes, 1-h NO_2 peaks, typically arising from gas cooking, can range between 0.4 and 1.5 ppm. See also [117] for acute and chronic inhalation toxicity studies with NO_2 and other propellants.

5.3 Emergency Exposure Limits for Nitrogen Dioxide

The original NIOSH Standard Completion Program (SCP) IDLH was 50 ppm. The originally chosen IDLH was based on earlier publications that stated that concentrations above 50 ppm are considered dangerous to humans for short exposures. Other

sources cited a rat 4-h LC50 of 68 ppm. The IDLH was later revised to 20 ppm [118, 119]. In September 2017, the IDLH was lowered further to 13 ppm [120]. Short-Term Public Emergency Guidance Levels (SPEGLs) proposed by the National Research Council are summarized in Table 5.

Table 5: Historical Short-Term Public Emergency Guidance Levels for nitrogen dioxide

Organization	Exposure duration	Maximum concentration, ppm
American Industrial Hygiene Association (1964) [121]	5 min	35
	15 min	25
	30 min	20
	60 min	10
National Research Council, Committee on Toxicology (1985) [122]	1 h	1
	2	0.5
	4	0.25
	8	0.12
	16	0.06
	24	0.04

Emergency exposure limits for NO₂ for military personnel, typically young, healthy males under close medical supervision, were established by the US National Research Council, Committee on Toxicology as follows: 10 min: 30 ppm; 30 min: 20 ppm; 60 min: 10 ppm [123].

5.4 Symptoms of NO₂ Inhalation Poisoning

Because NO₂ is not very soluble in water and body fluids, it can penetrate deeply into the respiratory system before a cough reflex is triggered. Coughing is triggered only at concentrations of 60 to 100 ppm, a relatively high concentration if one considers that 100 to 150 ppm can lead to acute poisoning within 30 to 60 min and that exposure to 200 to 700 ppm can be deadly even after short periods of inhalation.

The heinous aspect of NO₂ poisonings is that the damaging toxic effect often becomes apparent only several hours, possibly up to 24 h, after the incident [124]. The first symptoms are dizziness, headache, nausea, and weakness. At the next level of severity of poisoning, the victim will have difficulty breathing, experience shortness of breath, and struggle for air. This struggle may lead to death. If a poisoning incident progresses to this point, it is usually too late for medical help. If the symptoms are recognized early enough, oxygen inhalation is recommended as a first aid measure until professional medical help arrives.

The physiologically adverse action of NO_2 occurs through absorption in the lungs and into the bloodstream, where it disproportionates into nitrous acid and nitric acid, dropping the pH of blood below the point where it can effectively transport oxygen. Nitrate is not the main culprit. It is mostly the toxicity of nitrite that interferes with life-sustaining chemical reactions. Even after less serious nitrite poisoning incidents, the poisoning victim remains in an anemic state. Cases of acute NO_2 poisoning may lead to emphysema, accumulation of fluid in the lungs. This effect may take several hours to develop to its full level of severity.

5.5 Results of Laboratory Animal Exposure Tests

Chronic exposure of rats, mice, and guinea pigs to NO_2 (fumes from RFNA) for a duration of up to 4 h/day, 5 d/week, 6 months total showed that exposure to 4 ppm NO_2 caused no permanent detectable adverse effects [125]. At 9 to 14 ppm NO_2 lung damage was detected after only 6 weeks of testing. In another test series with male albino rats, the LC50 was 138 ppm after 30 min of inhalation, and 67 ppm after 4 h of inhalation [126, 127].

Most tests of animal exposure to toxic rocket propellants are conducted with only the oxidizer or only the fuel present. In real-life situations, where a missile or a launch vehicle with storable propellants malfunctions, there may be clouds of mixtures of nitrogen dioxide with fuel vapors that have not completely reacted because one component or another may be in excess. Spills very rarely happen at stoichiometric ratios of the offending propellants, and spilled propellants may not ignite instantly. Often the attempt to extinguish the flames of burning propellants releases clouds of incompletely burned intermediate reaction products.

Tests have been conducted in which animals were exposed to the clouds of partially reacted NTO and UDMH simulating a propellant spill and explosion. A “blast tube” was designed in which the propellants are injected simultaneously and allowed to react partially, simulating a propellant spill [128, 129]. The test animals were then exposed to the products of the incomplete reaction. A total of 168 healthy male rats were randomly divided into 3 groups and exposed to blast tube products for 10 min. The rats inhaling an excess of UDMH were designated the BU group, the rats inhaling an excess of N_2O_4 were designated the BN group, and the rats inhaling both UDMH and N_2O_4 were designated the BUN group. The clinical symptoms of the rats in the BUN group were aggravated progressively, the pulmonary alveoli were diffusely filled with pink exudate and large patchy hemorrhage, and pneumorrhagia and pneumoedema were aggravated. Cloudy swelling or hyaline degeneration occurred in the cardiac muscle cells in different degree and individual myocardial fiber was broken. The myocardial mesenchyme was loose and hemorrhage, and edema occurred. The pathologic change of the myocardium was aggravated. Dilation of the hepatic sinusoid and cloudy swelling in the hepatic cells were observed. The blood oxygen saturation in

all three groups decreased significantly at 3–12 h after injury and reached its lowest point at 3–6 h after injury. In addition to acute toxicity effects, the exhaust products from the blast tube may also be carcinogenic. After studying the immediate adverse effects, mostly on the lungs and dissolved gases in the blood system, additional tests looked at the presence of carcinogenic compounds, as indicated by their ability to create precancerous genes.

In another blast tube test, the animals were necropsied 3, 6, 12, 24, 48, and 72 h after exposure to observe the changes in pathomorphologic manifestation, blood gases, and gene expression [130]. The arterial oxygen saturation values of animals in all three groups decreased significantly at 3–6 h after exposure, and some of the animals died from respiratory failure.

In a similar test, 40 healthy mice, weighing from 18 to 22 g, were divided into 4 groups [131]. The mice were put into a 112-L cabinet and inhaled the partially reacted NTO/UDMH vapor mixture for 2 h. The exposure was repeated three times a day for 4 d, and then the mice were necropsied on the fifth day. The content of malondialdehyde (MDA) in serum and lipofuscin in liver homogenate and the activity of T superoxide dismutase (SOD) in serum were measured and it was found that **(1)** the content of serum MDA of 300-ppm group decreased significantly compared to that in the control ($P0.05$), **(2)** serum T SOD activity of the 60-ppm group and 300-ppm group decreased significantly compared to the control ($P0.01$), **(3)** the content of liver lipofuscin in the 9-ppm group increased significantly compared to the control ($P0.05$). It was concluded that low and moderate doses of liquid propellant mixtures can produce an abundance of free radicals but no oxidative damage.

It is difficult to find a common denominator in NO_2 inhalation pulmonary toxicity testing done with different animal species. Attempts were made to eliminate nasal variations among species and dermal absorption by administering the 200 ± 5 ppm ($376 \pm 9 \text{ mg/m}^3$) NO_2 -containing air directly to the lungs of rats for 15 min [132]. While most of the animal exposure tests were done with rodents, and it is difficult to extrapolate from rodent toxic effects to human exposure to this chemical, fewer animal exposure tests have been conducted with larger mammals, which would be more relevant to human NO_2 inhalation. Testing was done with 15- to 20-min exposures to either air (control) or 500 ppm NO_2 in sheep [133, 134]. Nose-only and lung-only routes of exposure were compared for effects on NO_2 pathogenesis. Histopathologic examinations of lung tissues were performed 24 h after exposure. Nose-only and lung-only routes of exposure were compared for effects on NO_2 pathogenesis. Bronchoalveolar lavage fluids from air- and NO_2 -exposed sheep were analyzed for biochemical and cellular signs of NO_2 insult. The influence of breathing pattern on NO_2 dose was also assessed. Five hundred ppm NO_2 exposure of intubated sheep (lung-only exposure) was marked by a statistically significant, albeit small, blood methemoglobin increase. The exposure induced an immediate tidal volume decrease and an increase in both breathing rate and inspired minute ventilation. Pulmonary function, indexed by lung resistance and dynamic lung compliance, progressively deteriorated after exposure.

Groups of rats were exposed to NO₂ for 3, 6, 12, 24, 48, and 72 h, and the long-term effects were studied during the post-exposure observation period of 2 months [135].

The comparative acute toxicity of NO₂ was studied in five species: mice, rats, guinea pigs, rabbits, and dogs [136]. Fifty ppm NO₂ was a critical concentration; below this value mortality rarely occurred with exposures of up to 8 h. A study was made of the sequential development of pathologic changes in the lung with grading of edema, congestion, interstitial irritation, bronchiolitis, and interstitial fibrosis. Acute deaths were characterized by marked bronchiolitis, desquamated bronchial epithelium, infiltration by polymorphonuclear cells, and edema fluid in the alveoli. Interstitial fibrosis occurred in about one-third of the surviving animals at 30 d and persisted in some for periods up to 6 months. Stress induced by exercise following exposure, by adrenalectomy, or by high levels of CO₂ increased mortalities.

Other tests were conducted in dogs and in rabbits [137]. In rabbits, after NO₂ exposure for 10 min, the observed pulmonary effects became more pronounced with increasing NO₂ concentrations (0, 125, 175, 250, 400, 600, or 800 ppm) (1 ppm NO₂ is equivalent to 1.88 mg/m³). The effects in rabbits were found to be broadly comparable to those in rats. See also [138].

5.5.1 Hematological Effects of NO₂ Inhalation on Blood Chemistry

Blood nitrite and nitrate of mice exposed to 5–40 ppm NO₂ were determined using naphthylethylenediamine and a Cu-Cd reduction column [139]. When mice were exposed to 40 ppm NO₂, nitrite became constant in 10 min. Nitrite declined rapidly, with a half-life of several minutes, after exposed mice were removed to fresh room air. Nitrate showed changes similar to those of nitrite; however, the concentration in the blood was higher and the half-life was longer. Dose-effect relationships were also determined at concentrations ranging between 5 and 40 ppm for 1 h of exposure. No increase of methemoglobin was observed at these concentrations. The addition of fresh mouse blood to sodium nitrite *in vitro* indicated a rapid conversion of nitrite to nitrate with an increase of methemoglobin, whereas addition to sodium nitrate caused no changes. The fate of inhaled NO₂ in the living body remains to be studied. Nitrogen dioxide inhalation affected red blood cells of rats and mice and caused changes in components of red cell membranes during *in vivo* exposure to NO₂ [140, 141].

5.5.2 Pulmonary Effects of NO₂ Inhalation

The relationship between respiratory function and morphological changes in 10 dogs exposed for 6 h to 69 ppm NO₂ was studied based on functional assessments of breathing pattern, breathing mechanics, forced expiration, gas exchange, and acid-base status [142]. Gross, microscopic, and ultrastructural evaluations were made of lung tissues from dogs killed at 0.1, 1.0, 2.0, 3.0, 7.0, and 14.0 d after exposure. Functional changes were similar to those reported for humans. The principal dysfunction was gas-exchange impairment, apparently resulting from foam in the

airways. Breathing-pattern alterations appeared to result from stimulation of neural receptors. Gas-exchange measurements provided the most useful indicators of the pulmonary damage observed in this study. See also [143, 144].

Quite often NO_2 inhalation toxicity studies in animals were conducted in parallel with or in combination with ozone exposure since both gases are constituents of atmospheric smog in polluted areas [145].

Table 6 is a summary of LC50 values obtained in animal tests, in comparison to the minimum concentration that resulted in human fatalities after only 1 min of inhalation. Some Safety Data Sheets (MSDSs) give the LC50 by inhalation in rats as 115 ppm/h.

Table 6: Median lethal NO_2 concentrations for inhalation in animals.

Animal	Inhalation LC50, ppm	Exposure duration
Mouse	1000	10 min
Rat	88	4 h
Guinea pig	30	1 h
Rabbit	315	15 min
Human	200 ^a	1 min

^aLowest published lethal concentration

Data source: [146]

It is already extremely hazardous for living beings to be exposed to NO_2 by itself or UDMH by itself, but the combination of the two poisons, as it may be encountered at launch sites after launch vehicle catastrophic failures, may aggravate the situation. The oxidative damage parameters of mice poisoned by inhaling gas mixtures containing NO_2 (N_2O_4) and UDMH were studied by exposing groups of mice, rats, or rabbits to simulated reacting hypergolic propellant spills [131, 147, 148] or to simulated launch site disasters with hypergolic fires and explosions and N_2O_4 releases [147, 149].

5.6 Human Volunteer Exposure Studies

Twenty human subjects with asthma and chronic bronchitis and 10 normal, healthy adults were exposed to 0.5 ppm NO_2 for 2 h in an environmental chamber [150]. Seven of the 13 subjects with asthma experienced breathing difficulty symptoms with exposure, while only one each of the subjects with chronic bronchitis and the healthy, normal group experienced symptoms. Exposure to NO_2 caused significant pulmonary function changes in decreased quasistatic compliance for both the 10 normal subjects and the 20 subjects with asthma and chronic bronchitis. In addition, functional residual capacity increased significantly for the 20 subjects with asthma and chronic bron-

chitis. It was concluded that exposure of subjects with asthma and chronic bronchitis to 0.5 ppm NO₂ for 2 h does not produce a significant decrement in their pulmonary function.

Ten healthy volunteers were subjected to six repeated exposures with 4 ppm NO₂ (7 mg/m³) for 20 min every other day [151]. Analysis of the recovered bronchoalveolar lavage fluid demonstrated that repeated exposures to NO₂ caused a lung cell response different from that reported after a single exposure. Amounts of lavaged alveolar macrophages, B-cells, and natural killer cells were decreased. Lymphocyte numbers in peripheral blood were reduced after exposure. These results suggested that repeated exposure to NO₂ adversely affects the immune defense and leaves inhalation victims to increased susceptibility to respiratory infections.

Eighteen non-smoking normal subjects (mean age = 25 ± 4 years) were exposed to filtered air or 2 ppm NO₂ gas for 1 h in a 30-m³ environmental chamber on different days, typically 1 week apart, in a double-blind randomized test [152]. Lung function tests included forced vital capacity, forced expiratory volume in 1 s, partial expiratory flow at 40% of vital capacity, functional residual capacity, and specific airway conductance and were measured before and after exposure. No significant changes were noted in the lung function tests after NO₂ exposure. These findings indicated that normal non-smokers exposed to 2 ppm NO₂ for 1 h develop an increase in airway reactivity to aerosol, which is not associated with changes in lung volumes, flow rates, or respiratory symptoms [153].

Fifteen subjects were exposed to nitrogen dioxide or air for 3 h in a double-blind, randomized fashion in a 45-m³ environmental chamber, with intermittent exercise sufficient to quadruple ventilation [154]. Pulmonary function was measured during and after exposure, and airway reactivity to carbachol was assessed before and after exposure. The 15 subjects were exposed to continuous 1.5 ppm NO₂ and underwent bronchoalveolar lavage 3.5 h after exposure. No significant symptomatic or pulmonary function changes could be detected in response to any of the NO₂ exposures.

Twenty-one healthy volunteers were exposed on separate occasions to air and 0.6 and 1.5 ppm NO₂ for 3 h [155]. Phlebotomy and bronchoscopy were performed 3.5 h after each exposure, and recovered cells were challenged with respiratory viruses *in vitro*. Blood studies revealed a 4.1% NO₂ dose-related decrease in hematocrit ($P = 0.003$). Circulating total lymphocytes ($P = 0.024$) and T lymphocytes ($P = 0.049$) decreased with NO₂ exposure. In healthy subjects, exposures to NO₂ at levels found indoors caused mild airway inflammation, effects on blood cells, and increased susceptibility of airway epithelial cells to injury from respiratory viruses. A no-effect level was established between 0.2 and 0.6 ppm NO₂ [156].

5.7 Eye and Skin Effects of Nitrogen Dioxide and Dinitrogen Tetroxide

If N_2O_4 is splashed into the eyes, rinse the eyes immediately with water and seek medical help for further treatment. Concentrations of 10–20 ppm NO_2 are mildly irritating to the skin and eyes.

Splashes of liquid N_2O_4 on the unprotected skin cause only a mild irritation because it will evaporate at typical body temperatures. If the liquid is allowed to remain in contact with skin for a longer time, it will cause acid burns comparable to those caused by 60 mass-% nitric acid. The affected area should be rinsed immediately with copious amounts of water and then neutralized with 1% sodium carbonate or sodium bicarbonate solution.

5.8 Prophylaxis Against NO_2 Poisoning

Ascorbic acid (vitamin C), glutathione, and/or α -tocopherol (vitamin E) may have a prophylactic effect against acute NO_2 inhalation toxicity [153, 157, 158].

Herbal medicine, like extracts from salvia roots, may alleviate some of the adverse effects caused by accidental inhalation of NO_2 . Groups of rats were exposed to 0.19 g/m^3 NO_2 for 10 min. Following inhalation, half of the rats were treated immediately with 9 g/kg salvia root extract by intravenous (i.v.) injection and 3 g/kg salvia root extract by intraperitoneal (i.p.) injection 3 h after the first injection. The treated group was less affected by the NO_2 inhalation, based on tissue examination and enzyme activity. The antioxidant activity of salvia root extract may be responsible for the protective effect [159].

5.9 Therapy for NO_2 Poisoning

Post-accident treatment with hyperbaric oxygen (HBO) improved the survival rates of rats exposed to near-fatal concentrations and durations of NO_2 in air [160]. In this experiment, 36 Wistar rats were divided into 3 groups: a control group (12), an NO_2 -exposed group (12), and an NO_2 -exposed plus hyperbaric oxygenation (HBO) treatment group (12). Blood gas changes were measured before and after HBO therapy. The arterial pH, $P_a\text{CO}_2$ (mm Hg), and $P_a\text{O}_2$ (mm Hg) of the HBO group (7.25 ± 0.20 , 52.4 ± 0.30 , 67.0 ± 3.0) had changed significantly from the NO_2 poisoning group (7.15 ± 0.19 , 83.2 ± 0.4 , 50.0 ± 2.0) and approached the values of the comparison group (7.32 ± 0.21 , 42.30 ± 0.20 , 75.0 ± 3.0). The survival ratio of the NO_2 group was 25.0%, but the survival rate of the HBO group was 50.0%.

Propellant-handling personnel should undergo routine periodic health examinations, and their medical records need to be reviewed for slow changes in body functions. Considerable information that is useful in evaluating the adequacy of control measures can be obtained by compiling and analyzing clinical laboratory results, physical findings, and subjective complaints. A detailed treatment procedure for acute exposures to hypergolic fuels or oxidizers was described [161].

Nineteen victims with pulmonary edema induced by accidental nitrogen dioxide poisoning in a rocket test site had to seek clinical care [162].

Dinitrogen tetroxide may cause acute lung injury and acute respiratory distress syndrome through the respiratory tract, skin, or inhalation. The acute lung injury has the characteristics of alveolar capillary membrane injury and pulmonary interstitial edema, and the clinical manifestations are acute respiratory distress and non-cardiac pulmonary edema. N-acetic acid cysteine, *salvia miltiorrhiza* extract, baicalin, ulinastatin, and penethyclidine hydrochloride combined with dexamethasone, which can remove free radicals, inhibit the inflammatory response or have strong activity against lipid peroxidation and may be able to prevent and control acute lung injury caused by N_2O_4 [163].

5.10 First Aid Administered to N_2O_4 Accident Victims

Prompt and effective decontamination is the most important first step in counteracting contamination by N_2O_4 to reduce the degree of injury and mortality significantly [164].

5.11 Nitrogen Dioxide Poisoning from Dinitrogen Tetroxide Accidents

Accident reports and case studies of nitrogen dioxide inhalation at sites of dinitrogen tetroxide spillage are discussed in the chapter on dinitrogen tetroxide.

Nitrogen Fluorides

Nitrogen can form four binary fluorides: nitrogen trifluoride (NF_3 , CAS RN [7783-54-2]); dinitrogen tetrafluoride (tetrafluorohydrazine, N_2F_4 , CAS RN [10036-47-2]); difluorodiazene (N_2F_2 , CAS RN [10578-16-2]); and azine fluoride (fluorine azide, FN_3 , CAS RN [14986-60-8]). There are numerous other ternary nitrogen fluorine compounds containing a third type of atom, the most significant of which are nitrosyl fluoride and nitryl fluoride.

Only nitrogen trifluoride, NF_3 , and dinitrogen tetrafluoride, N_2F_4 , are of interest as oxidizers for rocket engines. Nitrogen–oxygen fluorides will be discussed in a subsequent chapter on ternary fluorides, so the existence of nitrosyl fluoride (NOF), nitryl fluoride (NO_2F), and nitroxyl fluoride (“fluorine nitrate”; FONO_2) shall simply be mentioned here since they are relatives of the nitrogen fluorides. Nitryl fluoride, NO_2F , is a potentially useful oxidizer for high-energy rocket propellants. As indicated by the number of publications, all of these compounds received a lot of attention in the 1960s when the search for high-energy storable propellants was in full swing [1]. Since then, things have calmed down, and in the twenty-first century very little work is being done on these chemicals, mostly for non-rocket applications.

Dinitrogen tetrafluoride (“tetrafluorohydrazine”) was discovered in 1958 and has been in the center of attention for fluorine rocket propellant chemists for a decade or two.

Looking at the list of potential nitrogen fluorides, one wonders why the fluoride of pentavalent nitrogen has not yet been discovered. Nitrogen pentafluoride would make a good rocket propellant oxidizer. After all, if nitrogen can form a pentavalent oxide, why not form a pentavalent fluoride? Or is N_2O_5 a peroxide with O–O bonds? Theoretical chemists have calculated the orbital energies of higher bonding states of nitrogen, but it appears that NF_5 is not a possibility at this time. But, of course, that is what was said about noble gas fluorides prior to the 1950s. Up to this time, all attempts to synthesize NF_5 have been unsuccessful, although the attempts have been going on for a long time [2–4]. Radioactive tracer experiments using ^{18}F have been conducted but failed to show the ability to synthesize even a trace of NF_5 , and the failure was blamed mainly on steric reasons [5–7].

Nitrogen fluorides are not very active fluorinating agents, but they can be used for the synthesis of organic difluoroamino compounds. They are weaker oxidizers than ClF_3 or BrF_5 . Most rocket fuels do not ignite hypergolically with either NF_3 or N_2F_4 .

When comparing the boiling points of nitrogen hydrides and nitrogen fluorides (NF_3 , boiling point (b.p.) 144 K [–129 °C]; NH_3 , b.p. 240 K [–33 °C]; N_2F_4 , b.p. 200 K [–73 °C]; N_2H_4 , b.p. 386 K [113 °C]), one will notice that despite their higher molecular weights, all nitrogen fluorides boil much lower than their nitrogen hydride counterparts. The higher boiling points of the hydronitrogens are due to the hydrogen bonding between molecules.

The chemical N–F bond in NF_3 is a very strong bond, and NF_3 is much more stable than its other nitrogen halide counterparts such as NCl_3 or even NI_3 , which are notoriously sensitive and explosive nitrogen halides. Among the nitrogen trihalides it is the only one that has a negative enthalpy of formation. NF_3 is stable enough that, when released into the atmosphere, it diffuses up into the stratosphere and becomes a global-warming and ozone-depleting environmental hazard.

The following publications summarized in Table 1 provide summaries of the physical and chemical properties of nitrogen–fluorine compounds, including HNF_2 and ClNF_2 .

Understanding the nature of the electron cloud of nitrogen–fluorine and nitrogen–nitrogen bonds in nitrogen fluorides allows us to predict the thermal stability of yet unknown nitrogen fluorides and oxyfluorides of nitrogen [21–23]. The upcoming section on the molecular structure of N_2F_4 will provide more information on bond strengths and dissociation energies of N_2F_4 .

Hydrogen-containing nitrogen fluorides such as fluoroamine FNH_2 and difluoroamine F_2NH (Section 9) might be of interest as monopropellants were it not for their extreme sensitivity to explosions. It is even difficult to produce them in the pure state, and they are typically isolated in a matrix of a solid inert gas. The same applies to the chlorofluoroamines.

A substantial amount of effort has been devoted to the development of organic difluoroamino (“DOMINO”) compounds as monopropellants, plasticizers, and solid propellant binders. Difluoroamino compounds contain the $-\text{NF}_2$ group attached to an organic alkyl or aryl skeleton, making them more energetic but also more sensitive.

Many of these compounds are shock sensitive, similar to nitro compounds. These compounds are discussed in detail in *Encyclopedia of Oxidizers*, chapter “Difluoroamino Compounds.”

1 Nitrogen Trifluoride

Nitrogen trifluoride, also known as NF_3 , trifluoroamine, trifluoramine, nitrogen fluoride, trifluoroammonia, perfluoroammonia, perfluoroamine, CAS RN [7783-54-2], is a colorless gas that condenses at 144 K (-129°C) to a colorless liquid. With a formula weight of 71 g/mol, it contains 80.27 mass-% F and 19.73 mass-% N. Anyone who has ever worked with nitrogen trichloride or even nitrogen triiodide will be surprised how stable nitrogen trifluoride is in comparison to the other nitrogen halogenides.

Nitrogen trifluoride is the only second-period–element non-metallic fluoride that is currently still commercially available in compressed gas cylinders in the United States. Even the U.S. Department of Defense, Defense Logistics Agency lists it in its inventory to make it available to the Armed Forces for (sometimes classified) applications. The main reason for the commercial availability of NF_3 is that it is finding industrial applications in semiconductor chemical vapor deposition (CVD) equipment cleaning [24, 25] and as etchant for micromachining of silicon and silicon carbide by deep reactive ion etching [26]. The NF_3 is activated by passing it through a glow discharge. The destruction efficiency of NF_3 in the discharge as determined by mass spectrometry is typically 100%. The Si removal rates for NF_3 obtained at optimum settings of O_2 addition and microwave power are significantly higher than those for perfluorocarbon gases, which had been used before the advantages of NF_3 for this application were advertised. It has also been used as the oxidizer with thin metal wires in high-intensity flash bulbs for flash photography.

1.1 Preparation of Nitrogen Trifluoride

Nitrogen trifluoride was first prepared by Ruff in 1928. Of all the non-metallic fluorides, nitrogen trifluoride is the only one blessed with a string of patent applications for its production by electrochemical and non-electrochemical methods, so there seems to be an economic incentive to be in the NF_3 business. There appears to be a good industrial market for this chemical other than its prospective use as a rocket propellant or chemical rare gas–halide excimer laser reactant. See also [27].

1.1.1 Preparation of Nitrogen Trifluoride by Electrolysis of Ammonium Bifluoride

In all electrochemical NF_3 production processes, selection of the anode material is the most critical choice to make. This is a very corrosive environment, and few materials stand up to atomic fluorine without degradation. Candidate materials are graphite,

LiF-impregnated carbon, nickel, copper, Monel, and boron-doped diamond (BDD). A relatively high corrosion rate and passivation of nickel anodes are critical problems in this method. Deposition of nickel sludge consisting of NH_4NiF_3 on the cell bottom is another problem to be solved. Carbon (graphite) as an anode is free from corrosion and passivation, but it has problems such as the occurrence of anode effect, the breakdown of the anode, and the contamination of the product by CF_4 . Nitrogen trifluoride was first prepared by Ruff and coworkers in 1928 by electrolysis of molten anhydrous ammonium hydrogen fluoride NH_4HF_2 with a copper cathode and a graphite anode [2, 28, 29]. This method for production of NF_3 was eventually even patented, but the NF_3 yields were very poor [30]. The yields depended strongly on the type of electrode materials, and it appeared to be difficult to find the correct type of graphite. Instead of graphite, nickel has also been used as the anode material [31, 32]. All electrolytic methods for production of NF_3 may result in the formation of difluorodiazine (N_2F_2) and/or difluoroamine (F_2NH), potentially explosive by-products that need to be removed before they have a chance to accumulate in one of the cold traps. If the electrolyte is not absolutely dry, other by-products may be oxygen, nitric oxide, and nitrous oxide. Purification methods for crude NF_3 will be discussed in an upcoming section later in this chapter. In a divided cell drawing a current of 3000–4000 A having nickel anodes, extensive dilution of the gas streams with GN_2 was used to prevent explosive reactions between NF_3 and H_2 [33].

It is important that the NH_4HF_2 electrolyte be as water-free as possible to start with. In the presence of moisture, no NF_3 is formed initially, and the first NF_3 shows up only after days of operating the cell [34]. An electrolyte composition ranging from $\text{NH}_3 \cdot 2.2\text{HF}$ to $\text{NH}_3 \cdot 2.8\text{HF}$ gives good results. Nickel electrodes are preferred over graphite electrodes. The electrode voltage should be kept between 5.6 and 5.9 V. Other investigators producing NF_3 by electrolysis have observed the opposite, where the yield dropped off with time [35].

Substantial amounts of HF are carried out of the electrolyte with the NF_3 and H_2 evolved and need to be separated from the product stream. It would be best if the HF could be recycled into the process and not adsorbed on NaF, as is often done for small-scale operations. In order to minimize the HF carryout, the HF vapor pressure as a function of NH_4HF_2 /HF melt composition and temperature must be known [36].

Copper is often used as an electrode material, but in a melt of NH_4HF_2 during the production of NF_3 it does not survive very well. The electrochemical behavior of copper in anhydrous $1.37\text{HF} \cdot \text{NH}_4\text{HF}_2$ mixtures was investigated at 298 K (25 °C) using voltammetric and electrochemical impedance spectroscopic techniques [37]. The reaction mechanisms are complex, and the experimental results can be interpreted by considering the occurrence of adsorbed species and fluoride and oxide compounds of copper at oxidation states Cu(I) and Cu(II). Passivation does not protect the metal from further attack.

A very systematic study of different electrolyte compositions based on NH_4F with varying amounts of HF and the addition of other fluorides was done. The composition of the anode gas was analyzed by gas chromatography, and the performance of nickel anodes was also compared with that of carbon anodes [38]. With nickel anodes and the basic $\text{NH}_4\text{F} \cdot 2\text{HF}$ electrolyte, typical current efficiencies were 49.2% NF_3 , 20.1% N_2 , 9.26% O_2 , 4.83% N_2F_4 , 1.47% N_2F_2 , and 7.18% N_2O . When the current efficiency for NF_3 production on a nickel electrode versus current density was plotted, the efficiency leveled off at 70% for current densities above 100 mA/cm^2 ; 2.5% of the coulombs flowing were lost due to nickel anode corrosion. Four different anode metals were tested and the metal loss measured: The mass loss rate in $\text{g h}^{-1} \text{cm}^{-2}$ for the four metals was 1.94×10^{-5} , 2.27×10^{-5} , 2.12×10^{-4} , and 1.74×10^{-3} for Ni, Fe, Monel, and Cu, respectively. A skirt of Monel separating the anode and cathode space actually caused some hydrogen evolution on the wrong side of the diaphragm and explosions in the gas space. It was replaced with a polytetrafluoroethylene spacer. To avoid future problems, both anode and cathode gas spaces were purged with nitrogen during electrolysis from then on. The addition of KF to the $\text{NH}_4\text{F} \cdot 2\text{HF}$ lowered the vapor pressure of HF but increased the electric conductivity and viscosity of the melt. Besides KF, LiF, CsF, and NaF were also tested as electrolyte additives, but without measurable improvement of NF_3 yield.

Electrolysis of the melts of $\text{NH}_4\text{F} \cdot 2\text{HF}$ with and without metal fluorides such as LiF, NaF, KF, CsF, MgF_2 , or AlF_3 was conducted with a nickel anode [39]. The addition of LiF into the melt was most effective for increasing the NF_3 current efficiency and for minimizing the consumption of nickel anode. In contrast, KF in the melt decreased the current efficiency for NF_3 and other constituents in the anode gas as well as hydrogen generated at the cathode. It also worsened the consumption of the Ni anode. The concentration of nickel ion in the molten $\text{KF}/\text{NH}_4\text{F}/\text{HF}$ system was low compared with that in the melts of $\text{NH}_4\text{F} \cdot 2\text{HF}$ with and without alkali metal fluorides such as LiF and CsF because KNiF_3 was deposited on the cathode and the cell bottom.

Different anode metals were compared in the electrolytic formation of NF_3 from molten salts (NH_4FHF , KFNH_4HF , and CsFNH_4FHF) [40]. The current efficiencies for NF_3 formation on a Ni anode and a LiF-impregnated carbon (LiF/C) anode in the NH_4FHF melt increased with an increase of the current density and became constant at current densities higher than 120 and 50 mA/cm^2 , respectively. Current efficiencies on the Ni anode were greater than those on the LiF/C anode in the range of current density higher than 30 mA/cm^2 . On the other hand, the presence of KF in the melt reduced the NF_3 current efficiency on both the Ni and the LiF/C anodes, and the NF_3 current efficiency on the LiF/C anode in the KFNH_4FHF melt decreased with an increase of the current density. Product gases obtained with an LiF-doped carbon anode contained CF_4 , but only less than 1 vol-% CF_4 . Surface analysis methods showed that the oxide film on the Ni anode polarized in the NH_4FHF melt was composed of nickel difluoride with a small amount of nickel oxides such as NiO and Ni_2O_3 , some highly oxidized $\text{Ni}^{>2+}$ nickel fluoride, and oxyfluoride having plural

valences [41]. Consequently, nickel metal not only serves as a purveyor of electrons, but highly oxidized nickel fluorides on the Ni anode function as mediators of the electrochemical fluorination of ammonium ion. This effect would not be found with carbon electrodes.

The corrosion of nickel electrodes can be minimized by pre-saturating the electrolyte with Ni^{2+} ions [42]. Although the addition of complexes such as NiNH_4F_3 and $(\text{NH}_4)_3\text{FeF}_6$ in the melt was effective for minimizing the Ni or Fe anode consumption, the NF_3 formation was seriously affected [43]. Therefore, the allowable contents of Ni^{2+} or Fe^{3+} in the melt should be no more than 0.06 and 0.03 mol-%, respectively. Water in the melt retarded not only the anode consumption but also the current efficiency for NF_3 formation.

Instead of using plain nickel anodes, oxidized nickel anodes or composites pressed from nickel powder and NiO powder have performed well in the electrolysis of $\text{NH}_4\text{F} \cdot 2\text{HF}$ melts for the production of NF_3 [44]. The electrodes can be pre-treated by heating them in air [45].

A nickel electrode having 0.07 mass-% or less of Si content and containing a transition metal other than nickel has been patented [46]. The electrolyte must also contain a transition metal other than nickel.

Nickel/nickel oxide composite electrodes can be prepared from a mixture of Ni and NiO powders at 1173 K (900 °C) under 2000 atm pressure for 2 h by hot isostatic pressing (HIP). In electrolysis of molten $\text{NH}_4\text{F} \cdot 2\text{HF}$ at 373 K (100 °C) and at 25 mA/cm², the anode gas generated at the Ni-NiO composite anode was composed of NF_3 , N_2 , O_2 , N_2F_2 , N_2F_4 , and N_2O , and its composition was almost the same as that of a Ni sheet anode [47]. The best current efficiency for NF_3 formation was about 53% on the Ni/5 mol-% NiO composite anode, and it was almost the same as that of the Ni sheet anode. The anode consumption of the Ni-NiO composite was much smaller compared with that of the Ni sheet electrode.

Other nickel/metal oxide composites such as Ni/ Co_3O_4 , Ni/ MnO_2 , Ni/ Ag_2O , Ni/ Y_2O_3 , Ni/ La_2O_3 , Ni/ Nd_2O_3 , and Ni/ Sm_2O_3 systems were prepared by HIP and tested as electrodes in the $\text{NH}_4\text{F} \cdot 2\text{HF}$ electrolyzer [48]. Percentages of metal oxides in the nickel/metal oxide composite electrodes were 2, 5, and 10 mol-%. Composition of the anode gas evolved at every nickel-based composite electrode was almost the same as that on a nickel sheet electrode. Current efficiencies for NF_3 formation on Ni/ Y_2O_3 and Ni/ La_2O_3 composite anodes were almost the same as that on the nickel anode, whereas that on Ni/ Co_3O_4 composite anode was very small compared with that on the nickel sheet anode. In the cases of the Ni/ Co_3O_4 , the Ni/ MnO_2 , and the Ni/ Ag_2O composite anodes, the current efficiency for NF_3 formation decreased with an increase in the oxide concentration in the composite anodes. Current losses of the Ni/ Co_3O_4 composite anode were very large compared with the nickel sheet anode.

Nickel-based alloys, such as Ni/Co, Ni/Mn, Ni/Ag, Ni/Cu, Ni/Al, and Ni/Si, prepared by HIP at 1000 °C under 2×10^8 Pa pressure for 2 h, were employed as the anodes

for electrolytic production of NF_3 , but current efficiencies for NF_3 formation were not much better than that of the nickel sheet anode baseline, and the anode consumptions were almost the same or smaller compared with those of Ni sheet and hot isostatic-pressed Ni electrodes [49].

BDD thin-film electrodes combine electrical conductivity with chemical inertness and corrosion resistance. They can be prepared by a hot-filament CVD method on a carbon substrate using $\text{CH}_4/\text{H}_2/\text{B}(\text{OCH}_3)_3/\text{Ar}$.

The best current efficiency (72.4%) using BDD anode in $\text{NH}_4\text{F} \cdot n\text{HF}$ melts was obtained at 40 mA/cm^2 and an NH_4F -concentration of 33.3 mol% (the $\text{NH}_4\text{F} \cdot 2\text{HF}$ melt) [50]. An evaluation of electrolytic production of NF_3 using BDD anodes in molten $\text{NH}_4\text{F} \cdot 2\text{HF}$ showed that the current efficiency for NF_3 production was independent of the current density in the range of $200\text{--}1000 \text{ mA/cm}^2$ [51]. The average values of NF_3 current efficiencies on BDD anodes with boron concentrations of 2500 ppm were 32.3% at 80°C , 63.3% at 100°C , and 59.7% at 120°C . Galvanostatic polarization curves of BDD anodes with boron concentrations of 2500, 5000, 7500, 10000, and 12500 ppm in molten $\text{NH}_4\text{F} \cdot 2\text{HF}$ and a carbon anode in a molten $\text{NH}_4\text{F} \cdot \text{KF} \cdot 4\text{HF}$ were measured for comparison. The best current efficiencies for NF_3 production (70%) were obtained with BDD anodes containing 5000 ppm B. Electrode performance was measured during 1000-h tests, and there was little change in electrode performance. The mechanism on electrochemical fluorination seems to be as follows: At potentials higher than about 4 V, fluoride ion can be discharged to form $\text{F}^\bullet$ on an anode. The fluorine radical reacts with ammonia adsorbed on an anode and/or ammonium cation in the melt near the anode to produce $\text{NH}_2^\bullet$. The amino radical then reacts with fluorine radicals to form NF_3 . When current density and electrolyte temperature were varied, best yields (70%) were obtained with a current density of 450 mA/cm^2 at 100°C .

Metal fluoride (MgF_2 and CaF_2)-doped carbon anodes treated by pre-electrolysis were investigated for electrolytic production of NF_3 in molten $\text{NH}_4\text{F} \cdot \text{KF} \cdot 4\text{HF}$ at 373 K (100°C) [52]. The highest critical current density was 290 mA cm^{-2} . One anode was successfully used in the electrolysis at 100 mA cm^{-2} for 290 h, and the maximum NF_3 current efficiency was 55%. The metal fluoride-doped carbon anodes treated by pre-electrolysis have a high potential for improvement of the electrolytic production of NF_3 at higher current densities.

It is very important to separate the anode and cathode gas streams to prevent explosions. Purging with an inert gas will prevent explosions [53]. See also [54].

In the mid-1960s, while working at the DVL Institute for Rocket Propellants in Stuttgart, Germany, the author evaluated three different methods for the preparation of NF_3 . The best results were obtained by electrolysis of molten ammonium hydrogen fluoride ($\text{NH}_3 \cdot 2.5\text{HF}$) on nickel anodes [55]. Other processes for the preparation of NF_3 or N_2F_4 evaluated experimentally at DVL Stuttgart were the electrofluorination of urea or guanidine in anhydrous H_2F_2 at $258\text{--}253 \text{ K}$ (-15 to -20°C), but this resulted only in a mixture of reaction products, including COF_2 . At the attempt to purify the mixture of

reaction products by passing them through granulated activated charcoal, the charcoal ignited and combusted along with the polytetrafluoroethylene spacer that was meant to hold the charcoal in place.

At other organizations, instead of working with a melt of ammonium bifluoride at high temperatures, it was attempted to electrolyze ammonium bifluoride NH_4HF_2 in a large excess of H_2F_2 (anhydrous hydrogen fluoride [AHF]) as the solvent and electrolyte and operate at lower temperatures, but the only product was difluorodiazine $\text{FN}=\text{NF}$ [56–58]. Polarization curves of Monel electrodes in solutions of NH_4HF_2 in AHF did not show any diffusion-limited regions indicative of a potential-dependent stepwise reaction. The results indicated that the fluorination of NH_4HF_2 in AHF occurs by a radical mechanism involving anodically generated fluorine. Chronopotentiometric data, current-potential curves, and product yields versus time curves indicated that the fluorinating agent, during electrolysis, is a “loose” complex between $\cdot\text{F}$ and NiF_2 and/or CuF_2 . *Trans*- N_2F_2 was the only N-F product formed from the electrolysis of NH_4HF_2 in AHF.

The production of NF_3 by electrolysis of molten NH_4HF_2 was tested in a pilot plant that already bore some similarity to an industrial-scale production facility [59]. The composition of gases produced at the anode was analyzed as a function of current density, temperature, and electrolyte composition. The anode was made of the same carbon material that was also used for electrochemical production of elemental fluorine.

Nickel anodes used during production of NF_3 are heavily corroded, and dissolved nickel ends up in the spent electrolyte, but it can be recovered in the form of NiCO_3 for its metal value and purification of the electrolyte before it is recycled [60]. The recovery rate of nickel reached 97%.

1.1.2 Preparation of Nitrogen Trifluoride by Electrofluorination of Other Amino or Amido Compounds

Electrofluorination of organic compounds is a widely used method for synthesis of N–F compounds [61]. Some NF_3 is obtained by electrofluorination of urea dissolved in anhydrous hydrogen fluoride, but it is difficult to separate NF_3 from a host of unwanted byproducts (CF_4 , CO_2 , N_2 , COF_2 , N_2O , N_2F_2 , and OF_2) [62–65]. The mixture can barely be separated by fractionated distillation, but the distillate fraction may still contain about 1% CF_4 .

The electrofluorination of urea to nitrogen trifluoride at a carbon anode, in the system $\text{KHF}_2/\text{HF}/\text{CO}(\text{NH}_2)_2$, and the effect of current density, concentration of urea, and anode potential on the composition of the anodic product gas have been investigated [66]. By-products were N_2 , CO_2 , CO , O_2 , OF_2 , CF_4 , and F_2 . At optimum conditions (0.1–1 A/dm^2 ; 5.0–5.5 V, 2–3 mol-% of urea), the current efficiency of NF_3 production was 55%, whereas in $\text{KHF}_2/\text{HF}/\text{NH}_4\text{F}$ 75% may be achieved, and a better purity product would be obtained.

In the fluorination of urea, the main products were NF_3 , N_2 , COF_2 , and CO_2 , and small amounts of CF_4 , N_2O , and N_2F_2 were also found in the product [67]. The molar ratio of NF_3 to N_2 depended strongly upon electrolysis conditions and was found to increase with a decrease in the concentration of urea and with an increase in current density. In the fluorination of 1,1-dimethylurea, NF_3 , N_2 , CF_4 , CHF_3 , COF_2 , and CO_2 were mainly formed, with a small amount of CH_2F_2 and C_2F_6 .

Adding urea to a working NH_4F - HF - KF electrolysis system did not improve the yield of NF_3 [68].

Instead of urea, one can also subject guanidine to electrofluorination [69]. Electrolytes containing up to 40 mass-% guanidinium fluoride were still not saturated; they remained liquid and were good conductors of electrical currents. The partial pressure of HF above the electrolyte was very low, reducing carryover into the product cold trap. The crystal structure of dry guanidinium fluoride was studied by X-ray diffraction (XRD) as a measure of quality control to ensure purity of the ingredients used for NF_3 production. The current yield of all fluorinated products was 66% and that of NF_3 alone was 47%. The resulting mixture of NF_3 and CF_4 had an average molecular mass of 76, which corresponds to a molar ratio $\text{NF}_3 : \text{CF}_4$ of 2.5 : 1. Because the boiling points of the two gases are very similar, the mixture cannot be separated by fractionated condensation, but it can be separated by gas chromatography.

The electrofluorination of acetamide (CH_3CONH_2) or formamide (HCONH_2) in molten KH_2F_3 at 393 K (120 °C) produced a mixture of N_2 , O_2 , NF_3 , CF_4 , C_2F_6 , N_2O , CO_2 , and COF_2 [70]. The addition of 1.0 mass-% LiF into the electrolyte decreased the yield of NF_3 . Amorphous carbon was used as the anode and a Pt-rod as the reference electrode. It was suggested that CH_3CONH_2 or HCONH_2 would react chemically with atomic fluorine produced on the carbon anode film by the discharge of fluoride ions.

1.1.3 Preparation of Nitrogen Trifluoride by Direct Ammonia Fluorination

Nitrogen trifluoride and/or tetrafluorohydrazine can also be prepared by direct fluorination of ammonia:

However, the yield is very poor [71, 72]. The yield of NF_3 in an unpacked reactor was initially only 6% based on fluorine consumed but could be improved to 39–60% when the reaction was performed in a T-shaped packed copper reactor. With an excess of ammonia, some tetrafluorohydrazine was formed. One must perform this reaction in very dilute media if one does not want to chance ignition, such as in a rocket engine operating on fluorine and ammonia. The direct combustion of ammonia with an excess of fluorine does not give NF_3 [73].

Most patented processes for the production of NF_3 by direct fluorination of ammonia or ammonium salts operate in a melt phase instead of in the gas phase. There are only a few publications and patents about operating in the gas phase. Nitrogen tri-

fluoride can be prepared by reacting fluorine gas with ammonia gas in the gas phase, where the reaction is performed at 203 K (70 °C) or less in the presence of a diluting gas [74]. The concentration of fluorine gas in the diluent gas is 3 mol-% or less, and the concentration of ammonia gas fed is 6 mol-% or less. The fluorine gas is fed in portions from two or more gas inlets, or the ammonia gas is fed in portions from two or more gas inlets.

If an excess of ammonia with diluent gas is used in a gas/gas reactor, the solid NH_4F salt will clog the reactor. A reactor has been described with a scraper that continuously removes the deposits from the wall of the reactor [75].

All the following patents perform the reaction of fluorine and ammonia in a melt of ammonium bifluoride instead of in the gas phase. One of the first patents in this category was [76], which described a process for the production of NF_3 by the direct fluorination of ammonium bifluoride at temperatures above 260 °F and below 400 °F. The HF/NH_3 ratio was maintained at 2.0 to 2.5. Diluted fluorine gas and ammonia were bubbled through the stirred melt at opposite locations. In a similar vein, [77] patented the synthesis of NF_3 from elemental fluorine gas and a source of ammonia in a gas-liquid phase reaction where the HF/NH_3 ratio is at least 2.55 and the reaction melt is agitated with a mixing apparatus. The source of nitrogen can be either NH_3 bubbled into the melt or an ammonium salt added in the form of NH_4F or NH_4HF_2 .

If the process is carried out continuously, the loss of HF from the melt and the generation of waste-melt products constitute expensive waste-disposal problems. The process can be optimized to minimize the amount of hazardous waste generated [78]. A stripping gas can be used to carry HF and reaction products from the melt.

An ammonium bifluoride melt can be suspended in an inert, heated perfluorocarbon bath while ammonia and elemental fluorine are injected continuously at separate locations into the agitated melt, producing NF_3 in yields up to 90% (based on converted fluorine) [79].

Nitrogen trifluoride can be produced by rapidly ejecting a jet of fused ammonium fluoride salt into a reactor through a nozzle while aspirating fluorine gas into the stream (similar to an aspirator vacuum pump) and recirculating the melt from the bottom of the reactor [80].

The direct fluorination of molten ammonium bifluoride can be carried out in two stages, first at low temperature and then in a second reactor at higher temperature with an excess of fluorine, which removes all unwanted by-products [81]. The fluorine feed stream can be diluted with hydrogen fluoride [82]. The momentum of the injected hydrogen fluoride carrier gas that carries the fluorine can also serve to stir the reacting ammonium bifluoride melt and ensure uniform mixing in the reaction zone [83].

In another variant of the same process, the molten NH_4HF_2 and fluorine are co-injected at the inlet of a packed reactor operating at lower temperature, and the gaseous products are subsequently finished in a second reactor at higher temperature [84].

Instead of mechanical agitation, the gaseous reactants can be mixed by static mixing elements as they push the molten salt through the reactor [85]. Gaseous ammonia and gaseous fluorine are introduced on opposite sides of the first static mixing element. The reaction is conducted at a temperature only 5°C higher than the melting point of the ammonium bifluoride/hydrogen fluoride mix.

Instead of fluorinating molten ammonium fluoride, diluted fluorine can be reacted in a batch process with a packed bed of a solid, granular ammonium metal fluoride, such as ammonium cryolite $(\text{NH}_4)_3\text{AlF}_6$, and NF_3 emerges at the other end of the reactor [86, 87]. Ammonium cryolite $(\text{NH}_4)_3\text{AlF}_6$ is prepared in such a way that it has a large surface area to interact with the fluorine [88, 89].

The $(\text{NH}_4)\text{AlF}_4$ is then reconverted to $(\text{NH}_4)_3\text{AlF}_6$ and recycled:

1.1.4 Preparation of Nitrogen Trifluoride by Combined Electrochemical Processes

Combined electrochemical processes are essentially ammonia direct-fluorination processes, except the fluorine does not arrive at the factory in compressed-gas bottles but is produced in an electrolytic cell that is adjacent to and combined with the ammonia fluorination reactor. In this case, the fluorination is carried out by bubbling ammonia and fluorine in a melt of a low-melting ternary mixture of $\text{HF/KF/NH}_4\text{HF}_2$. If ammonia is fluorinated in a reactor separately from an electrolysis unit, the hydrogen fluoride formed in the reaction is an unwanted process waste. It would have to be collected and trucked back to the fluorine factory. If ammonia is fluorinated in a molten bath containing a ternary flux of hydrogen fluoride, ammonium fluoride, and potassium fluoride that is part of the fluorine electrolyzer, the HF formed in ammonia fluorination is absorbed into the bath and can be sent (pumped) to the adjacent electrolyzer to be converted back to fluorine [90]. The flux circulating in the electrolyzer and the NF_3 reactor has the same three ingredients, but in different proportions. Ammonia gas is bubbled through the molten $\text{NH}_4\text{F/HF/KF}$ bath to replenish what has been consumed. HF is added prior to entering the fluorine electrolysis cell. In the reactor, an excess of fluorine is maintained and the apparatus is under pressure, which minimizes the by-products difluorodiazine and tetrafluorohydrazine.

1.1.5 Preparation of Nitrogen Trifluoride by Other Non-Electrochemical Processes

Other methods for preparation of NF_3 were reported in the literature, but none of these alternative methods has gained any significance, such as the reaction of azine fluoride (“fluorine azide”) N_3F with oxygen difluoride [91] or nitrosyl fluoride or chlorine trifluoride [92].

The fluorination of N_2O at $>373\text{ K}$ ($>100^\circ\text{C}$) gives a mixture of NF_3 and NOF [93]:

Small amounts of NF_3 (besides NF_2H and N_2F_2) are detected if one passes dilute fluorine gas over sodium amide powder [94].

If one replaces the sodium amide with metal nitrides (Li_3N , Be_3N_2 , Mg_3N_2 , BN , Si_3N_4 , TiN , VN), the NF_3 yield decreases to below 1%, but more difluorodiazine can be found in the reaction products [95–97]. All of the substances fluorinated gave predominantly nitrogen as a volatile product. No nitrogen trifluoride was observed in the case of the metallic type nitrides, TiN and VN . Small quantities of nitrogen trifluoride were observed in the other experiments. Nitrous oxide and carbon tetrafluoride were detected in all of the runs as the result of impurities in the fluorine and possibly in the nitrides.

It has also been possible to synthesize NF_3 directly from the elements in a glow discharge at 76 K (-197°C) and $20\text{--}40\text{ mm Hg}$. A 15-kV , 30-mA luminous tube transformer was used as the power source for the discharge. Starting with a mix of 25% N_2 and 75% F_2 , the yield was up to 30% [98]. The synthesis of nitrogen trifluoride from the elements appears analogous to the synthesis of oxygen fluorides from the elements under essentially the same conditions. However, unlike the polyoxygen fluorides, variations of the stoichiometry of the fluorine/nitrogen mixtures did not lead to other nitrogen-fluorine compounds such as N_2F_2 .

Nitrogen trifluoride was obtained from nitrogen and fluorine in a barrier discharge with 1.5–2% yield by using a circulation system [99]. The reverse reaction, the decomposition of the nitrogen trifluoride into the elements in the barrier discharge, reached 98%.

The degree of conversion of stoichiometric fluorine/nitrogen mixtures to nitrogen trifluoride increased monotonically with increasing specific energy at current strengths of 8, 12, and 25 mA and specific energies up to $200\text{--}450\text{ W}\cdot\text{h/L}$ [100]. The dependence of the degree of conversion on the current strength was extreme: A current strength of 12 mA was most favorable for the synthesis of nitrogen trifluoride. The absence of tetrafluorohydrazine in the reaction product of fluorine with nitrogen was explained by the low stability of tetrafluorohydrazine in a glow discharge. Argon is an inert additive in the synthesis of nitrogen trifluoride.

If pure NF_3 is passed through a glow discharge under conditions similar to its formation from the elements, it decomposes into the elements [101]. It is obvious that the yield of NF_3 in the synthesis from the elements by this method is limited by the reverse reaction unless the NF_3 is continuously and immediately removed from the discharge zone by condensing it.

Operating at much higher temperatures in an electric arc discharge, reminding one of the Birkeland process for production of HNO_3 from air and water, passing nitrogen and CF_4 or SF_6 through the hot zone, and quenching the reaction products quickly

thereafter gave only a very poor yield of NF_3 , CF_3NF_2 , or any other useful product [102, 103]. Only 1% of the nitrogen fed to the arc was converted to a product.

Passing a mixture of nitrogen and fluorine gas through an arc discharge reactor and immediately quenching the effluent in liquid nitrogen results in the formation of a mixture containing NF_3 and N_2F_4 [104]. By varying the $\text{F}_2:\text{N}_2$ ratio, NF_3 can be produced to the exclusion of N_2F_4 .

NF_3 can be prepared by chemical fluorination of urea in a solution of anhydrous H_2F_2 at temperatures from 253 to 273 K (-20 to 0°C) and molar ratios of fluorine to the starting compounds of not over 3 [105].

1.1.6 Purification of Nitrogen Trifluoride

For many industrial applications, the quality of NF_3 produced by electrolysis or other methods may not be adequate. The main contaminant in NF_3 produced by electrolysis with carbon electrodes is CF_4 , which is very difficult to separate from NF_3 because the physical properties of the two compounds are so similar. The two gases can be separated by gas chromatography, but preparative gas chromatography on an industrial scale would be impractical. Therefore, a number of alternative separation and purification methods have been developed and patented. Other unwanted contaminants are tetrafluorohydrazine, difluorodiazine, and nitrous oxide. The purity requirements for NF_3 to be used as rocket propellant or laser propellant are less stringent than the purity requirements for NF_3 to be used in the semiconductor industry. The need for purification methods such as those described in this chapter was driven mostly by the semiconductor etching and CVD equipment-cleaning applications.

Separation of nitrous oxide from nitrogen trifluoride is possible by fractionated distillation (condensation) or filtration of the solid N_2O from the liquid NF_3 at very low temperatures (78 K [-195°C]) [106, 107].

A continuous method for separation of NF_3 from CF_4 and C_2F_6 contaminants is based on column absorption of the organic compounds in a trickle tower fed with chilled chloroform or tetrachloromethane [108]. The less soluble NF_3 accumulates in the gas phase. Preparation and purification of NF_3 has its own set of hazards and potential for accidents [109].

A **safety warning** must be issued to anyone who might consider removal of contaminants in NF_3 by adsorption on activated charcoal, which in at least one case has resulted in an explosion with severe personal injuries [110, 111]: 600 g of activated, granulated charcoal had been dried at 393 K (120°C) and was placed in a steel cylinder and cooled to 173 K (-100°C). About 25 g of NF_3 were condensed into the cylinder within 10 min, and shortly after it all condensed, the cylinder **exploded**, throwing glowing charcoal all over the place and setting the methanol/dry ice cold bath on fire. In order to retain both N_2F_2 and N_2O , the active charcoal has to be cooled to at least 193 K (-80°C). At 273 K (0°C) only N_2O is absorbed. The adsorption of contaminated

NF₃ on charcoal is an exothermic process and caused temperature increases of 40–70 °C, which may be enough to ignite the mixture.

Difluorodiazene N₂F₂ contamination in NF₃ must be removed before NF₃ is further purified by adsorbing other contaminants on zeolites because N₂F₂ may react exothermically with aluminosilicates and cause explosions. Dinitrogen difluoride contamination present in nitrogen trifluoride gas can be removed by heating the nitrogen trifluoride gas to 423–873 K (150–600 °C) in a metallic vessel, the inner wall of which is lined with a solid fluoride, and then cooling the gas and passing it through a gas washing flask with a solution of potassium iodide or sodium sulfite [112]. A reactor made from nickel and coated on the inside with nickel fluoride is the preferred equipment for this process [113].

Difluorodiazene, F–N=N–F, formed as a contaminant during NF₃ synthesis, may accumulate in cold traps and is detonable, which is why it has to be removed. The gas to be purified by removal of dinitrogen difluoride can be passed through a packed bed of nickel spheres heated to 422–811 K (300–1000 °F) [114].

Nitrogen fluoride that is purified by condensing and by fractionated distillation can be freed from dioxygen or dinitrogen contamination if the condensation and distillation are carried out in the presence of helium, neon, or argon as a purge gas [115]. Purification of nitrogen trifluoride and removal of N₂F₂ and N₂F₄ by passing it through activated charcoal is a dangerous process, even if the adsorbent is wetted with water. The patent fails to warn users of this method about the explosive hazard [116].

Difluorodiazene N₂F₂ contamination in NF₃ can be removed from the crude NF₃ gas by passing the gas through an aqueous solution containing both an alkali metal iodide and an alkali metal sulfite or alkali metal hydrogen sulfite [117].

Tetrafluoromethane is difficult to separate from NF₃ because the boiling points are so similar. Separation is possible by adsorbing the mixture on a desiccated erionite synthetic zeolite at 243 K (–30 °C), pumping off the CF₄ or purging it out with an inert gas, and desorbing and condensing the purified NF₃ [118]. Nitrogen fluoride thus purified contained no more than 10 ppm CF₄.

A low-temperature two-column distillation with an extractive cryogenic liquid countercurrent stream of an inert cryogenic liquid in the first trickle column can effectively free NF₃ from more volatile and less volatile contaminants. The extractive distillation in the first column allows more volatile contaminants to pass. The NF₃ and less volatile contaminants dissolved in the auxiliary fluid from the bottom of the first column are fed to the second column, where NF₃ is withdrawn from the top of the column and thereby separated from the auxiliary fluid and less volatile contaminants [119].

A two-step purification method is to first remove unreacted F₂ and HF without forming oxygen difluoride or nitrogen oxides, and then to remove nitrogen oxides by adsorption on a molecular sieve [120]. One must remember that N₂F₂ and NF₃ may react explosively with SiO₂ and silicates.

NF_3/CF_4 mixtures can be separated by bringing them into contact with a polyacrylonitrile-based carbon molecular sieve so that at least a portion of one or more impurities are adsorbed by the molecular sieve without a significant adsorption of the NF_3 [121].

The pure and mixed gas permeabilities of Teflon AF2400, Teflon AF1600, and Hyflon AD60 membranes toward NF_3 and CF_4 were measured to determine whether membrane gas separation can be applied to purify NF_3 of CF_4 [122]. It was shown that thermal annealing of the solution cast films was necessary to reach optimum performance, wherein all membranes studied had a preferential permeation of NF_3 rather than CF_4 . The Teflon AF and Hyflon AD60 membranes displayed rather high pure and mixed gas selectivities ($\alpha(\text{NF}_3/\text{CF}_4)$) considering the high free volume of the polymers. Hyflon AD60 displayed the highest NF_3/CF_4 pure and mixed gas selectivity of just above 12, albeit with a rather low NF_3 permeability index of about 1.9 Barrer.

A high-purity nitrogen trifluoride with an impurity content of <10 ppm can be obtained by ultraviolet (UV) or infrared (IR) radiation to cause the dissociation of chemical bonds in the impurities to form dissociation products and thereby make the subsequent removal of the contaminants from the NF_3 easier [123]. The wavelength of the UV or IR light is selected such that one or more chemical bonds of the contaminants dissociate to form more reactive dissociation products.

1.2 Physical Properties of Nitrogen Trifluoride

The physical properties of nitrogen trifluoride are well characterized and are summarized in Table 2.

Table 2: Physical properties of nitrogen trifluoride.

Property	SI units	MKS units	References
Molecular mass	71.0019 g/mol	14.0841 mol/kg	
Boiling point	144.15 K	−129.0 °C	[31]
	144.1 K	−129 ± 0.3 °C	[124]
	144.14 K	−129.01 °C	[125]
Melting point	66.49 K	−206.67 °C	[31]
	64.6 K	−208.5 °C	[126]
	71.019 K	−202.13 °C	[125]
Triple point	66.373 or 66.361 K	−206.79 °C	[32]
	66.46 K	−206.69 °C	[127]
	66.36 K	−206.79 °C	[125]

Solid NF_3 undergoes a phase transition at 56.62 K. The heat capacity of nitrogen trifluoride has been measured from 12 to 144 K. The heat of transition was +1.514 kJ/mol (361.8 cal/mol) [128]. With its low melting entropy (1.43 eu) and high molecular mobility, solid NF_3 in its high-temperature phase can be classified as a plastic crystal.

The melting point of pure NF_3 was reported as 64.6 K (−208.5 °C) [126]. See also [8, 13, 129, 130].

1.2.1 Density of Nitrogen Trifluoride

The density of liquid NF_3 in the range from 78 to 170 K (−195 to −103 °C) can be expressed by the following polynomial equation [31]:

$$\rho = 2.103 - 3.294 \times 10^{-3}T - 4.675 \times 10^{-6}T^2$$

where ρ is the density in g/cm^3 and T is the temperature in kelvin. The estimated uncertainty in these values is $\pm 0.1\%$. The raw data are tabulated in Table 3.

Table 3: Density of liquid nitrogen trifluoride.

Temperature, K	Density, g/cm^3
78.05	1.819
79.44	1.812
87.23	1.780
92.22	1.760

1.2.2 Vapor Pressure of Nitrogen Trifluoride

The vapor pressure of NF_3 has been measured by several investigators. The data obtained between 86 and 144.5 K can be expressed by the following equation [128]:

$$\log p_v = 1.869858 \log T - \frac{673.5828}{T} - 0.0078335T + 4.64615$$

where p_v is the vapor pressure in mm Hg and T is the temperature in kelvin. Similar measurements led to a slightly different equation, related to the data in Table 4 [31]:

$$\log p_v = 6.77966 - \frac{501.913}{T - 15.37}$$

where p_v is the vapor pressure in mm Hg and T is the temperature in kelvin. Another equation covers the higher pressure range up to the critical pressure:

$$\log p_v = 4.27264 - \frac{613.33}{T}$$

where p_v is the vapor pressure in atm and T is the temperature in kelvin.

Table 4: Vapor pressure of nitrogen trifluoride.

Temperature, K	Vapor pressure, mm Hg
89.33	1.00
98.99	5.92
108.58	24.79

1.2.3 Viscosity of Nitrogen Trifluoride

The viscosity and velocity of sound of gaseous nitrogen trifluoride in the temperature range 225–375 K and up to 3.4 MPa were measured using a Greenspan acoustic viscometer [131]. The velocities of sound measured up to 3.4 MPa were fitted by a virial equation of state that predicted gas densities within the uncertainties of the equations of states available in the literature (Figure 1).

Figure 1: Viscosity of gaseous nitrogen trifluoride. (Graph created by Schmidt 2020, based on data from [131].)

1.2.4 Thermal Conductivity of Gaseous Nitrogen Trifluoride

The thermal conductivity of gaseous nitrogen trifluoride was estimated from other physical properties as listed in Table 5, in comparison to viscosity data obtained by similar computational methods.

1.2.5 Solubility of Nitrogen Trifluoride

NF₃ is slightly soluble in water without undergoing hydrolysis chemical reaction. The solubility in water at 101 kPa is 1.4×10^{-5} mol NF₃/mol H₂O.

NF₃ dissolved in anhydrous H₂F₂ without reaction or compound formation. The solubility of NF₃ in H₂F₂ was measured for pressures up to 1.2 MPa (12 atm) and followed Henry's law [133]. The slope of the solubility curve showed that F₂ was about half as soluble in H₂F₂ as NF₃. Simultaneously compressing mixtures of NF₃ and F₂ into H₂F₂ did not result in compound formation.

Table 5: Estimated thermal conductivity and viscosity of gaseous nitrogen trifluoride.

Temperature, K	Thermal conductivity, $\text{mW m}^{-1} \text{K}^{-1}$	Viscosity, $\mu\text{Pa s}$
200	10.50	11.70

700	52.61	35.59
750	57.46	37.40

Data source: [132]

Liquid NF_3 in a molar ratio of 1 : 1 is completely miscible with LOX or OF_2 at 77 K, with Ar at 85 K, with LOZ at 90 K, and with CF_3Cl or CF_4 at 90 K, but it forms two separate layers with O_2F_2 at 130 K, ClF_3 at 140 K, H_2F_2 at 140 K, and ClF at 150 K [134].

1.2.6 Critical-Point Properties of Nitrogen Trifluoride

Critical-point data of nitrogen trifluoride are listed in Table 6.

Table 6: Critical-point data of nitrogen trifluoride.

Property	SI units	MKS units
$t_{\text{crit.}}$	$233.89 \pm 0.10 \text{ K}$	$-39.26 \pm 0.10 ^\circ\text{C}$
$P_{\text{crit.}}$	$4.517 \pm 0.017 \text{ MPa}$	$44.72 \pm 0.17 \text{ atm}$
$V_{\text{crit.}}$		$123.8 \text{ cm}^3/\text{mol}$

1.2.7 Thermodynamic Properties of Nitrogen Trifluoride

Thermodynamic properties of nitrogen trifluoride are listed in Table 7.

Table 7: Thermodynamic data of nitrogen trifluoride.

Property	SI units	Other units	References
Standard enthalpy of formation, gas, $(\Delta H)_{298}$	$-124.3 \pm 7.5 \text{ kJ/mol}$	$-29.7 \pm 1.8 \text{ kcal/mol}$	[135]
	-132.09 kJ/mol	-31.57 kcal/mol	[132]
	$-127.2 \pm 5.0 \text{ kJ/mol}$	$-30.4 \pm 1.2 \text{ kcal/mol}$	[136]
	-123.58 kJ/mol	-29.536 kcal/mol	[137]
Standard enthalpy of formation, liquid $(\Delta H)_{298}$	-142.6 kJ/mol	-34.08 kcal/mol	[137]
Standard entropy of formation, gas $(S)_{298}$	$260.77 \text{ J mol}^{-1} \text{ K}^{-1}$	$62.32 \text{ cal mol}^{-1} ^\circ\text{C}^{-1}$	[132]
Entropy, gas, at 144 K	$228 \text{ J mol}^{-1} \text{ K}^{-1}$	$54.50 \text{ cal mol}^{-1} ^\circ\text{C}^{-1}$	[128]
Heat of vaporization $(\Delta H)_{\text{evap}}$ (at 144 K [$-129 ^\circ\text{C}$])	11.58 kJ/mol	2.769 kcal/mol	[31]
	11.58 kJ/mol	2.769 kcal/mol	[128]
Heat of vaporization $(\Delta H)_{\text{evap}}$ (at normal boiling point)	11.59 kJ/mol	2.77 kcal/mol	[38]
Heat of fusion $(\Delta H)_{\text{melt}}$ (at 66.3 K [$-206.8 ^\circ\text{C}$])	398 J/mol	95.11 cal/mol	[128]
Heat of fusion	398 J/mol	95.12 cal/mol	[38]

The heat of reaction of

is $-834.7 \pm 0.9 \text{ kJ/mol}$ ($-199.49 \pm 0.22 \text{ kcal/mol}$) NF_3 [138]. It is difficult to derive the enthalpy of formation of NF_3 from this test because of the uncertainty of the heat of solution of HF.

A calorimetric method gave the enthalpies of formation $\Delta H^\circ_{\text{f}298}$ of several nitrogen fluorides, based on their reaction with aqueous KI solutions in a calorimeter in which gases were bubbled through the liquid [139]. The values of $\Delta H^\circ_{\text{f}298}$ recommended for NF_3 , N_2F_4 , *cis*- N_2F_2 (identical for *trans*- N_2F_2), NF_2Cl , NF_2H , FNO, and FNO_2 were listed, although the values for N_2F_4 , FNO, NF_2NO , and FNO_2 were provided with a caution of being uncertain, with the need for further experimental verification. From the $\Delta H^\circ_{\text{f}298}$ and $\Delta S^\circ_{\text{f}298}$ values, the thermodynamic bond energies for the nitrogen fluorides were calculated.

The heat of formation of NF_3 was measured by two different methods [140]. The heat of dissociation measurements gave $\Delta H_{\text{f}} = -31.44 \pm 0.3 \text{ kcal/mol}$, and the heat of reaction of NF_3 and sulfur gave $\Delta H_{\text{f}} = -31.75 \pm 0.2 \text{ kcal/mol}$. An average of -132.2 kJ/mol (-31.6 kcal/mol) NF_3 was employed to calculate values for $\text{HF}(\text{aq})$, which compared well with other work reported in the literature.

Literature values for the enthalpy and entropy of formation of NF_3 , N_2F_4 , NF_2Cl , *cis*- N_2F_2 , *trans*- N_2F_2 , F_2NN , FNO, and FNO_2 were collected and summarized, and expressions were derived for the temperature dependence of the free energy of formation of these substances [141]. The thermodynamics of several reactions for the synthesis of NF_3 , N_2F_4 , and FN_2F involving the substances listed above were examined.

The dissociation energy of difluorine and the heat of formation of hydrogen fluoride affect all methods for determining the heats of formation of fluorides. Methods used are fluorine bomb calorimetry at constant volume, fluorine flame calorimetry at constant pressure, explosion (decomposition) calorimetry, solid-state calorimetry, and solution calorimetry [142].

For additional thermodynamic properties of NF_3 , see also [143, 144].

The heats of formation of NF_3 , the hypothetical NF_5 , NFO, NFO_2 , NF_3O , N_2F_2 , N_2F_4 , N_3F , NF_3BF_3 , NFOBF_3 , NFO_2BF_3 , and NF_3OBF_3 were calculated using atomization reaction and formation reaction quantum mechanical computation methods, and the thermodynamic functions of these compounds were calculated [145]. Results showed that formation reaction quantum mechanical computation methods in conjunction with the G3 theory can accurately evaluate the heats of formation of these compounds. The results agreed well with experimental data.

1.2.7.1 Heat Capacity of Nitrogen Trifluoride

The heat capacity of gaseous NF_3 as a function of temperature can be calculated from the Shomate equation:

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + \frac{E}{\tau^2}$$

where C_p is the heat capacity in $\text{J mol}^{-1} \text{K}^{-1}$; A, B, C, D, and E are constants; and τ is the absolute temperature in kelvin divided by 1000. The coefficients are listed in Table 8. The same coefficients (and others) are used for formulas expressing the standard enthalpy of formation and the standard entropy of the vapor. These equations were curve-fitted from data covering ranges from 298 to 1000 K and from 1000 to 6000 K.

Table 8: Constants for vapor-phase thermodynamic properties of nitrogen trifluoride.

Temperature, K	298–1000	1000–6000
A	26.45610	82.54781
B	142.2606	0.345728
C	−137.6134	−0.071941
D	47.68505	0.005089
E	−0.404491	−4.482487
F	−146.5375	−169.6763
G	253.7876	340.7860
H	−132.0893	−132.0893

Data source: [132]

The saturation heat capacity C_σ of liquid NF_3 from the triple point to near the critical point can be calculated by the following formula [127]:

$$C_\sigma = A + BT + CT^2 + DT^3 + ET/(T_c - T)^{1/2}$$

The subscript σ , which in Greek stands for the letter s, refers to property values for the saturated liquid. The parameters A through E are listed in Table 9 and are also

Table 9: Heat-capacity parameters for liquid nitrogen and liquid nitrogen trifluoride.

	N_2	NF_3
A	$\text{JK}^{-1} \text{mol}^{-1}$	$\text{JK}^{-1} \text{mol}^{-1}$
B	$\text{JK}^{-2} \text{mol}^{-1}$	$\text{JK}^{-2} \text{mol}^{-1}$
C	$\text{JK}^{-3} \text{mol}^{-1}$	$\text{JK}^{-3} \text{mol}^{-1}$
D	$\text{JK}^{-4} \text{mol}^{-1}$	$\text{JK}^{-4} \text{mol}^{-1}$
E	$\text{JK}^{-1.5} \text{mol}^{-1}$	$\text{JK}^{-1.5} \text{mol}^{-1}$

Data source: [127]

shown in comparison for data for LN_2 . There is a shallow minimum in C_p of NF_3 at a temperature of about 110 K. T_c is 234 K.

The velocity of sound was measured in gaseous NF_3 using a highly precise acoustic resonance technique [146]. The measurements spanned the temperature range 200–425 K and reached pressures up to the lesser of 1500 kPa or 80% of the sample vapor pressure. The data were analyzed to obtain the constant-pressure ideal-gas heat capacity C_p as a function of temperature. The values of C_p were in agreement with those determined from spectroscopic data. The velocity-of-sound data were fitted by virial equations of state to obtain temperature-dependent density virial coefficients. Two virial coefficient models were employed, one based on square-well intermolecular potentials and the other based on a hard-core Lennard-Jones intermolecular potential. The resulting virial equations reproduced the velocity-of-sound data to within $\pm 0.02\%$ and may be used to calculate vapor densities with relative standard uncertainties of 0.1% or less.

1.2.7.2 Enthalpy of Formation of Nitrogen Trifluoride

The vapor-phase excess enthalpy above the standard enthalpy of formation $\Delta H^\circ_{f,298}$ of NF_3 can be calculated from the Shomate equation:

$$H^\circ - H^\circ_{298.15} = A\tau + \frac{B\tau^2}{2} + \frac{C\tau^3}{3} + \frac{D\tau^4}{4} - \frac{E}{\tau} + F - \Delta H^\circ_{f,298}$$

where A, B, C, D, E, and F are constants and τ is the absolute temperature in K divided by 1000. The coefficients are the same as those listed in Table 8. The same coefficients (and others) were used for a formula expressing the heat capacity of the vapor (Section 1.2.7.1). These equations were curve-fitted from data covering a range from 298 to 6000 K from [147].

Thermodynamic functions of NF_3 were derived from spectroscopic data for the temperature range 200–2000 K [148]. Earlier investigations of the molecular constants were less accurate or were outright incorrect.

The enthalpy of $\text{NF}_4^+(\text{G})$ can be extrapolated from the other (N, F) and (N, O, F) compounds. The enthalpies of solid NF_4^+ salts are close to those of corresponding NO_2^+ salts, and from this an exothermic heat of formation for NF_4^+F^- was predicted [149]. This compound NF_5 is not expected to be stable at room temperature.

1.2.7.3 Enthalpy of Dissociation of Nitrogen Trifluoride

The enthalpies of explosion of mixtures of hydrogen and excess NF_3 were measured in a bomb calorimeter [150]. From the measurements, the enthalpy of dissociation of an excess (10 or 100% excess NF_3) of NF_3 was derived, and the enthalpy of formation was calculated to be $-131.5 \pm 1.2 \text{ kJ/mol}$ ($-31.44 \pm 0.30 \text{ kcal/mol}$).

1.2.8 Optical Properties of Nitrogen Trifluoride

Spectra of NF_3 in all regimes of the electromagnetic spectrum have been measured for several reasons: NF_3 is a very symmetrical molecule in the shape of a spinning top, similar to ammonia, and thus is easy to model. Spectroscopic studies were done to measure the inertia moments of the spinning top-shaped molecule and compare it to that of ammonia. Spectroscopy is needed to identify contaminants in NF_3 and verify its purity, an important property for its applications in the semiconductor processing industry. NF_3 is a greenhouse gas that may accumulate in the upper atmosphere and cause global warming or destruction of the ozone layer. For this reason, its spectra and its photolysis have been studied by many chemists. Spectra of NF_3 and its decomposition products and potential reaction products with F_2 would also be of interest in the search for the so-far unknown NF_5 , which would be an even more energetic oxidizer for rocket propellants. Also, if NF_3 is used as a source of fluorine atoms in rare gas halide excimer laser systems, its spectra and vibrational energy states must be known. All of these causes together explain why there are several hundred publications on NF_3 spectra, but only a few of those are referenced here.

1.2.8.1 Infrared Absorption Spectra of Nitrogen Trifluoride

The structure and the IR spectra of NF_3 and PF_3 are very similar. The IR spectra of NF_3 and PF_3 were investigated with a prism instrument in the range of 250–5000 cm^{-1} [151]. The fundamental frequencies for NF_3 were reported as $\nu_1(\text{A}_1) = 1032 \text{ cm}^{-1}$, $\nu_2(\text{A}_1) = 647 \text{ cm}^{-1}$, $\nu_3(\text{E}) = 905 \text{ cm}^{-1}$, and $\nu_4(\text{E}) = 493 \text{ cm}^{-1}$. From these numbers, the force constants as well as thermodynamic functions could be calculated for both molecules.

The IR spectrum of gaseous nitrogen trifluoride has been investigated with prism instruments in the range of 400–3000 cm^{-1} , and the Raman spectrum of liquid nitrogen trifluoride has been investigated in the range of 400–2000 cm^{-1} , [152]. The fundamental frequency assignment made from the infrared data is as follows: $\nu_1(\text{A}_1) = 1031 \text{ cm}^{-1}$, $\nu_2(\text{A}_1) = 642 \text{ cm}^{-1}$, $\nu_3(\text{E}) = 907 \text{ cm}^{-1}$, and $\nu_4(\text{E}) = 497 \text{ cm}^{-1}$. The corresponding Raman shifts in the liquid were $\nu_1(\text{A}_1) = 1050 \text{ cm}^{-1}$, $\nu_2(\text{A}_1) = 667 \text{ cm}^{-1}$, $\nu_3(\text{E}) = 905 \text{ cm}^{-1}$, and $\nu_4(\text{E}) = 515 \text{ cm}^{-1}$. The interpretation of the overtone and combination bands in the IR spectrum may differ from that of earlier interpretations.

An intensive study has been made of the degenerate bands of NF_3 , to verify the theory that a Beer-Lambert-type law should hold for spectrometer tracings of IR bands in an intermediate-pressure range, providing a number of conditions are fulfilled [153]. It was found that the Beer-Lambert law held for T and T_0 at every frequency in the P and R branches of ν_4 and across the whole ν_3 band when sufficient NF_3 had been added to pressure-broaden the lines. Values for the N–F bond dipole moment were derived from the IR data.

The absolute IR intensities of the fundamental vibrations of NF_3 have been measured [154]. The results were interpreted in terms of the N–F bond moment (μ), its derivative ($\partial\mu/\partial r$), and the unshared pair moment on the N atom ($\mu_{\text{u.p.}}$). The bond mo-

ment obtained from the A_1 bending mode was found to be in the vicinity of 1 D. $\mu_{u.p.}$ was in the vicinity of either 1.2 or 1.7 D, depending on the sign assumed for the molecular dipole moment. There was a striking difference in the values of $(\partial\mu/\partial r)$ from the two symmetry species, with $(\partial\mu/\partial r)(A_1)$ in the range of 1.5–2 D/Å and $(\partial\mu/\partial r)(E)$ in the vicinity of 4.5 D/Å.

An approximate potential function has been determined for NF_3 by using the four fundamental frequencies, the experimentally determined rotational distortion constant DJ , and physical arguments based on the absolute intensity results [155]. The rotational distortion constants have been calculated as a function of the force field. Using the approximate potential function, values of the valence type force constants and the rotational distortion constant DK were then calculated.

The IR spectrum of nitrogen trifluoride was measured over the range 400–3500 cm^{-1} , and the rotational fine structure of a number of bands was resolved [156]. The nature of this rotational structure was of special interest because few such studies had been done with oblate symmetric top-shaped molecules. From the parallel-type bands, estimates have been made of the coefficients α_B relating different vibrational states, and a detailed study of the perpendicular-type bands associated with ν_3 and ν_4 has made it possible to derive the Coriolis coefficients $\zeta_3 = +0.81$ and $\zeta_4 = -0.90$ and other coefficients α_A . A number of other bands due to overtones, harmonics, and difference transitions have been recorded and assigned.

The ν_4 perpendicular band of NF_3 was measured at a resolution of about 0.035 cm^{-1} [157]. At this resolution, the appearance of the band was extremely sensitive to the effect of ℓ -type resonance and unambiguously shows that the ℓ -type doubling constant q_4 is positive. Matching calculated spectra with the observed one resulted in $\nu_0 = 493.43 \text{ cm}^{-1}$ and $\alpha_4^c = -5.3 \times 10^{-4} \text{ cm}^{-1}$.

The high-resolution ν_4 and $(\nu_4 + \nu_2)$ IR bands of NF_3 and the ν_6 IR band of CF_3H (another spinning top) have been investigated in detail using an ℓ -type resonance calculation computer program [158]. By means of the computer simulation technique, the shapes of the observed P, Q, and R branches could be accurately reproduced and the frequencies of all the fine structure “lines” in the P and R branches precisely matched. The analysis provided accurate values of all the band constants whose determination was not possible from the microwave spectra. A band structure investigation showed that the observed P and R branch “lines” arise primarily from clusters of closely spaced PPK(J) and RRK(J) lines of a given J and that in these bands the peaks of these P and R “lines” generally correspond to the $K \equiv J$ components of the PP(J) and RR(J) clusters, respectively.

The IR spectrum of a typical NF_3 sample was measured as part of an effort to develop a military specification and analysis methods for NF_3 [159] (Figure 2). At the same time, the IR spectrum of a synthetic mixture of seven likely contaminants with known concentrations was recorded. Poor sensitivity at the test conditions that were used and overlap of absorption bands allowed only NO_2 , CF_4 , and N_2O in a mixture with NF_3 to be determined by IR without scale expansion.

Figure 2: IR spectrum of nitrogen trifluoride. (Reproduced and modified from [159].)

The IR spectrum of dissolved NF_3 was measured in liquid-argon solution [160]. Because the sample of NF_3 used for the experiments was contaminated with N_2O , it was also necessary to measure the spectrum of N_2O in liquid-argon solution so that the impurity bands could be identified unambiguously. In the observed spectrum of NF_3 , it was possible to identify 29 overtone and combination bands in addition to the vibrational fundamentals. The wave numbers of the NF_3 bands were compared with the corresponding numbers determined from the gas-phase spectrum.

The intensities of the binary overtone and combination bands in the IR spectrum of NF_3 have been measured both in the gas phase and in liquid-argon solution and compared [161]. The observed intensities were interpreted in terms of a simple model that ascribed all the intensity of the binary overtones and combinations to anharmonic coupling with the fundamentals; i.e., a model in which the second derivatives of the dipole moment with respect to the normal coordinates were assumed to be zero. The agreement between the observed intensities and the calculated ones was very good for the bending modes but less satisfactory for the stretching modes.

High-resolution (0.004 cm^{-1}) IR spectra of all of the fundamental bands of nitrogen trifluoride have been obtained, and rotational analysis of these bands produced better band constants than had previously been reported [162].

The microwave and far-IR rotational spectrum in the ground vibrational state of $^{14}\text{NF}_3$ has been observed and analyzed up to $J=60$ using a tunable sideband spectrometer in the far-IR region [163]. The resulting molecular constants were (in MHz) $B_0 = 10681.092679(39)$, $D_J = 14.61109(11) \times 10^{-3}$, $D_{JK} = -22.77154(71) \times 10^{-3}$, $H_J = 0.019529(95) \times 10^{-6}$, $H_{JK} = -0.09847(96) \times 10^{-6}$, $H_{KKJ} = 0.1490(10) \times 10^{-6}$, $L_{JK} = -0.00072(12) \times 10^{-9}$, and $(eQq)_N = -7.0854(18)$. The millimeter-wave spectrum of $^{15}\text{NF}_3$ has also been observed and analyzed, providing the following slightly different

values of the rotational constants: $B_0 = 10629.47940(23)$, $D_J = 14.3234(12) \times 10^{-3}$, $D_{JK} = -22.2093(33) \times 10^{-3}$.

As part of an international spectroscopy effort, several accurate experimental values of the α^C and α^B rotation–vibration interaction parameters and ω_i , χ_{ij} , and g_{ij} vibrational constants were extracted from high-resolution Fourier-transform infrared spectroscopy (FTIR), millimeter wave, and centimeter wave investigations of the spectra of the oblate symmetric top–shaped molecule $^{14}\text{NF}_3$ [164–167]. The band-centers used were those of the four fundamentals, overtones, combinations, and hot bands identified in the region between 400 and 2000 cm^{-1} . Comparison of obtained constants with the ones measured previously, by IR spectroscopy at low resolution, revealed orders-of-magnitude higher accuracy of the new values, with wave numbers accurate to six places after the decimal point. The agreement between recent values and those determined by *ab initio* calculations employing the TZ2Pf basis was excellent.

The $\nu_1 + \nu_4$ (E, $\nu_0 = 1523.0407 \text{ cm}^{-1}$) IR absorption band of the oblate symmetric spinning top–molecule $^{14}\text{NF}_3$ has been studied by FTIR spectroscopy with a resolution of $2.5 \times 10^{-3} \text{ cm}^{-1}$, and in total, 1885 rovibrational transitions up to $K_{\text{max}} = 70 = J_{\text{max}}$ have been assigned [168]. Assuming the $\nu_1 = \nu_4 = 1$ vibrational state as isolated, the non-zero weighted experimental data were fitted to 26 free parameters with a standard deviation better than the spectral resolution. The experimental anharmonicity constant $\chi_{1,4}$ was determined as $-2.383249(49) \text{ cm}^{-1}$.

Laboratory measurements of NF_3 IR spectra gave an integrated IR absorption cross-section of $7.04 \times 10^{-17} \text{ cm}^2 \text{ molecule}^{-1} \text{ cm}^{-1}$ over the spectral region 200–2000 cm^{-1} [169]. The radiative efficiency was calculated to be $0.21 \text{ W m}^{-2} \text{ ppbv}^{-1}$, and the 100-year global warming potential, relative to carbon dioxide, was predicted to be 17200. These values were approximately 60% higher than previously published estimates, primarily reflecting the higher IR absorption cross-sections reported.

The IR spectra of NF_3 in the range of 900–4500 cm^{-1} were calculated by the model Hamiltonian and seemed to describe the N–F stretching modes accurately with only four numbers of parameters. It only predicted the higher overtones but also showed good agreement with the few observed data [170]. See also [171].

1.2.8.2 Raman Fluorescence Spectra of Nitrogen Trifluoride

In the Raman spectrum of gaseous nitrogen trifluoride, all four fundamentals have been observed at 500 cm^{-1} (E), 649 cm^{-1} (A_1), 910 cm^{-1} (E), and 1035 cm^{-1} (A_1) [172]. The molecular vibrations were assigned on the basis of polarization data and line shape.

The Raman spectrum of gaseous NF_3 was recorded, and the band contours of ν_3 (E) and ν_4 (E) were analyzed to determine the intensity ratio between the contributions of $\gamma \pm 1$ and $\gamma \pm 2$ [173]. The Raman profiles were studied in the crystal and in the liquid between 60 and 185 K. The intense IR lines $\nu_1(A_1)$ and $\nu_3(E)$ showed complex structures made up of two peaks at low temperature, similar to the structures of the intense IR lines of crystals and which are due to a particularly strong transition dipole coupling.

The NF_3 molecules rotate more easily about the main axis, with a ratio between the mean angles of rotation about the main axis and the other axis, respectively, equal to ~ 3 at 78 K. The Coriolis perturbation was found to reduce the contribution of the spinning motion to the line width of ν_4 , by a factor of 3 owing to the large value of the Coriolis constant.

1.2.8.3 Ultraviolet Absorption Spectra of Nitrogen Trifluoride

Because of the suspected contributions of NF_3 as a greenhouse gas to global warming and atmospheric chemistry, the UV absorption spectra and their photolysis have been investigated extensively.

In the electronic absorption spectrum of NF_3 at low pressures, the long wavelength limit of absorption was at about 960 Å in agreement with the lowest ionization potential of the molecule (939 Å) [174]. Quantitative intensity measurements showed a smooth decrease of the absorption coefficients to effectively zero at about 1800 Å, with no indication of even partly resolved electronic transitions.

The absorption spectra of liquid NF_3 or N_2F_4 have been measured at low temperatures in the near UV region of the spectrum [175]. It was shown that the liquid-phase absorption spectra did not differ much from the spectra in the gaseous phase. Therefore, the elementary absorption event was characterized by the cross-section of photon absorption by an individual molecule. The absorption cross-sections of these molecules were represented in the liquid phase, which did not differ significantly from absorption cross-sections of these molecules in the gaseous phase.

The absorption coefficient of nitrogen trifluoride at 147 nm was determined using two Pyrex cells in series. The absorption coefficient of nitrogen trifluoride was found to be $k = 136 \pm 3 \text{ (atm at 298 K)}^{-1} \text{ cm}^{-1}$ (base e) [176].

Nitrogen trifluoride is an atmospherically persistent greenhouse gas that is primarily removed by UV photolysis and reaction with $\text{O}(^1\text{D})$ atoms. Therefore, the NF_3 gas-phase UV absorption spectrum, $\sigma(\lambda, T)$, was measured at 16 wavelengths between 184.95 and 250 nm at temperatures between 212 and 296 K [177]. A significant temperature dependence was observed in the wavelength region most relevant to atmospheric photolysis (200–220 nm), with a decrease in $\sigma(210 \text{ nm}, T)$ of $\sim 45\%$ between 296 and 212 K. Atmospheric photolysis rates and global annually averaged lifetimes of NF_3 were calculated, giving lifetimes from 610 to 762 years and global lifetimes from 484 to 585 years. The NF_3 global warming potential is of the order of 13300 to 19700.

1.2.9 Microwave Spectra of Nitrogen Trifluoride

The microwave absorption spectrum of NF_3 molecules trapped in an argon matrix in the region of 18–50 GHz was measured, but no microwave absorption in excess of 1 db was observed, 1 db being the smallest signal that could be detected by the microwave spectrometer used in this experiment [178].

The microwave spectra of two isotopic species of the NF_3 molecule were investigated in the excited vibrational states [179]. The vibration–rotation interaction constants α_v^B for the ν_1 , ν_2 , ν_3 , and ν_4 states were found to be -43.45 , $+38.65$, $+78.81$, and $+4.48$ MHz for $^{14}\text{NF}_3$, and -38.41 , $+40.14$, $+75.67$, and $+4.64$ MHz for $^{15}\text{NF}_3$, respectively. The equilibrium rotational constant, B_e , was then derived to be 10761.91 ± 0.2 MHz for $^{14}\text{NF}_3$ and 10710.63 ± 0.2 MHz for $^{15}\text{NF}_3$, from which the equilibrium bond length was determined to be $r_e(\text{N}-\text{F}) = 1.365 \pm 0.002$ Å and the bond angle $\alpha_e(\angle \text{FNF}) = 102^\circ 22' \pm 2'$. A set of linear relations was derived between cubic potential constants from the observed α_v^B and ℓ -type doubling constants.

The microwave spectra for the $J=2 \leftarrow 1$ and $J=3 \leftarrow 2$ transitions in NF_3 were measured and analyzed for two isotopic species of NF_3 in the excited vibrational states [180]. The ν_4 and $\nu_2 + \nu_4$ satellites showed spectral patterns characteristic of the ℓ -type resonance, with the splitting of the center lines amounting to more than 80 MHz. The ζ_4 was found to be -0.895 for $^{14}\text{NF}_3$ and -0.888 for $^{15}\text{NF}_3$. The ν_3 satellites also showed the pattern of the ℓ -type resonance, but slight discrepancies were found between the calculated and the observed spectra and cannot be accounted for unless third-order terms are taken into consideration.

The ν_4 band of NF_3 , $\nu_0 = 493.423 \text{ cm}^{-1}$, has been studied by FTIR spectroscopy with a resolution of $3 \times 10^{-3} \text{ cm}^{-1}$. Strong intensity perturbation by $\ell(2, 2)$ resonance was revealed. The more than 5000 IR assignments were complemented by 132 millimeter-wave measurements in the regions 140–250 and 340–470 GHz, by seven new or formerly reported $J=1-0$ and $3-2$ microwave frequencies and by 134 $\Delta J=0$, $\Delta k=\Delta \ell=\pm 2$ direct ℓ -type centimeter-wave transitions in the region 8–26 GHz with $J_{\text{max}}=22$ and $(k-\ell)_{\text{max}}=15$ [181]. The rotational data enabled detection of splittings caused by $\ell(2, -4)(t)$ and $(0, 6)(h_3)$ interactions in excess of those by $\ell(2, 2)(q)$ effects. The sets of molecular constants obtained from the merged data reproduced the IR observations with $\sigma = 0.24 \times 10^{-3} \text{ cm}^{-1}$, the millimeter-wave data with $\sigma = 29 \text{ kHz}$, and the centimeter-wave measurements with $\sigma = 3 \text{ kHz}$.

The submillimeter-wave spectrum of $^{14}\text{NF}_3$ has been measured, and the ground state rotational spectrum has been reanalyzed, including the $K=3$ splittings [182]. The quadratic, cubic, and semi-diagonal quartic force field has been calculated at the CCSD(T) level of theory, employing a basis set of at least polarized valence triple-zeta quality. This force field has been used to predict the spectroscopic constants, including the parameters specific to the doubly degenerate vibrational states. The calculated values were found to be in good agreement with the available experimental data. See also [183, 184].

1.2.10 Photoelectron XPS Spectra of Nitrogen Trifluoride

The He(I) resonance photoelectron spectra of gaseous nitrogen trifluoride and nitrogen oxide trifluoride were recorded and compared to those of boron trifluoride and carbon tetrafluoride [185, 186]. The first band in the He-I photoelectron spectrum of

NF₃ was obtained at sufficiently high resolution to reveal vibrational structure [187]. The bifurcated nature of the band was interpreted as a transition from pyramidal NF₃ to pyramidal NF₃⁺, the latter having a lower barrier to inversion since one of the lone electrons is missing. The span of the Franck-Condon region in the transition was sufficient to surmount the barrier, whose magnitude can be estimated from the spectrum to be ~0.75 eV. This is one of the very few cases for which an accurate experimental measurement of an inversion barrier is known.

The interaction of NF₃ with elemental silicon surfaces has been investigated using X-ray photoelectron spectroscopy (XPS) [188]. Si(100) surfaces were subjected to plasmas created by NF₃ gas mixtures and ion bombardment from NF₃-generated ion beams as a means of reproducing the ion component of semiconductor plasma etching under controlled conditions. NF₃ plasma impingement on Si led to the appearance of a high binding-energy component in F1s XPS spectra, possibly as a result of neutral interstitial fluorine being incorporated into the Si lattice as a result of an ion-damage mechanism.

1.2.11 Electrical Properties of Nitrogen Trifluoride

The dielectric breakdown voltage of NF₃ in comparison to SF₆ and air was measured with two 25-mm (1-in)-diameter copper sphere electrodes spaced 0.76–10.2 mm (0.03–0.4 in) apart with voltages applied from 10 to 70 kV AC [35]. SF₆ is widely used as a dielectric in transformers and high-voltage switches. NF₃ is a much better dielectric than either SF₆ or air, but concerns about its reactivity prevented its use in high-voltage electrical equipment. With a 10.2-mm (0.4-in) gap, the breakdown voltage for NF₃ was 70 kV, for SF₆ was 58 kV, and for air was 26 kV.

1.2.12 Magnetic Properties of Nitrogen Trifluoride

1.2.12.1 Nuclear Magnetic Resonance Spectra of Nitrogen Trifluoride

Direct comparisons between ¹⁹F nuclear magnetic resonance (NMR) spectra of liquid and gaseous F₂, OF₂, and NF₃ had not been reported prior to 1966 [189]. Previous sources had listed the chemical shift of liquid NF₃ as -145 ± 1 ppm (in relation to CFCl₃). The chemical shifts of liquid and gaseous F₂, OF₂, and NF₃ are listed in Table 10.

Table 10: ¹⁹F NMR shifts in liquid and gaseous F₂, OF₂, and NF₃.

	¹⁹ F NMR shifts ^a		
	F ₂ (ppm)	OF ₂ (ppm)	NF ₃ (ppm)
Liquid at 77 K	-422 ± 1	-249 ± 1	-142 ± 1
Gas	-419 ± 1	-248 ± 1	-138 ± 1
Difference gas–liquid	3	1	4

^aIn relation to CFCl₃ reference.

Data source: [189]

As can be seen in Table 10, the chemical shifts for liquid F_2 , OF_2 , and NF_3 were all lower than the corresponding shifts in the gas. This downfield shift due to liquefaction is similar to that observed in the proton magnetic resonance studies of the first-row hydrides

A combined nuclear quadrupole resonance (NQR) and NMR study has been made of solid NF_3 . The quadrupole coupling constant and asymmetry parameter of ^{14}N have been determined and the low-temperature torsional oscillation frequencies of the molecule in the solid calculated by fitting the temperature dependence of the resonance frequencies to Bayer theory [190]. The constants obtained were as follows: $3e^2q_0Q/4h = 5.3012 \pm 0.0005 \times 10^6 \text{ s}^{-1}$, $\eta_0 = 0.00112 \pm 0.00002$, $\nu_x = 1.505 \pm 0.005 \times 10^{12} \text{ s}^{-1}$, and $\nu_y = 1.003 \pm 0.003 \times 10^{12} \text{ s}^{-1}$, respectively, where the first two parameters are for the rigid lattice at 0 K. Above about 35 K, and particularly near the phase transition at 56.6 K, Bayer theory is inadequate to explain the observed temperature dependence. The line width decreased from 42 kHz at about 35 K to 1 kHz at 65 K, just below the melting point, but did not exhibit any noticeable discontinuity at a phase transition (56.62 K). The line width became very narrow before the solid melted, which was suspected to be due to the onset of hindered rotation of the NF_3 molecule about its triad axis below the transition temperature and the occurrence of additional large-amplitude motions above the transition. The data were reanalyzed in terms of a one-motion process and a two-motion process [191]. Although the data showed no apparent discontinuity at the phase transition, the two-motion analysis gave much better agreement with experimental data. See also [192].

The ^{14}N NMR shift in NF_3 at 143 K was +238 ppm in relation to the shift in aqueous nitrite ion [193].

The difluoroamino $\bullet NF_2$ free radicals, having a lone electron, of course are paramagnetic, but based on measurements with doublet rotational Zeeman spectroscopy, there is a modest contribution of diamagnetism in the molecule that should not be neglected [194].

1.2.13 Molecular Structure of Nitrogen Trifluoride

The molecular structure of NF_3 is often compared to that of ammonia on the one side and to that of N_2F_4 on the other side. The decomposition of NF_3 and N_2F_4 produces difluoroamino $\bullet NF_2$ free radicals that are relatively stable. The heat of formation of the difluoroamino free radical was found to be $37.2 \pm 10.5 \text{ kJ/mol}$ ($8.9 \pm 2.5 \text{ kcal/mol}$) [22]. The NF_2-F bond in NF_3 is the weakest bond in NF_3 , in contrast to ammonia, in which the NH_2-H bond is the strongest bond:

Bond energy

NF_2-F	238.91 kJ/mol
$NF-F$	297.06 kJ/mol
$N-F$	297.06 kJ/mol

The strength of the $\text{NF}_2\text{—F}$ bond is $239 \pm 10.5 \text{ kJ/mol}$ ($57.1 \pm 2.5 \text{ kcal/mol}$), while the average NF bond strength in NF_2 and N_2F_4 is 297 kJ/mol (71 kcal/mol). For comparison, the strength of the N—N bond in N_2F_4 , as determined from appearance potential data, is 86.6 kJ (20.7 kcal), which is in excellent agreement with the value 82.8 kJ (19.8 kcal) found by thermal measurements. Compared to other fluoroamines, the N—F bond in NF_3 is relatively short.

A separation of the effects of substituent groups into distinct σ and π contributions and the influence of the σ and π contributions on Hamiltonians and wave functions of various cores have proved useful for describing several diverse phenomena in N—F compounds [23]:

- (1) the “anomalous” difference in bond strengths in NF_3 and NF_2 where the N—F bond in NF_3 is weaker than that in NF_2 ;
- (2) the non-constancy of the δ_K value for F in ionization potentials of NF_3 and CF_3 , whereas other substituent group effects were constant;
- (3) the similarity between the effect of F on ionization potentials of $\bullet\text{NF}_2$ and of $\bullet\text{CF}_3$.

The repulsion between an atom and a lone pair of electrons, such as may exist on nitrogen atoms, affects properties of ammonia and nitrogen trifluoride. The repulsion force constants were estimated using a one-electron theory [195]. A new derivation was shown for the method of introducing forces by the lone pair and subtracting lone-pair motion from the vibrational secular equation. The vibrational force constants for NF_3 were examined with this model in mind.

General valence force-field constants for NF_3 have been calculated using very accurate frequency data, Coriolis coupling constants (ζ), and centrifugal distortion constants [148]. The calculated constants were in excellent agreement with the experimental data. Mean amplitudes of vibration were calculated by several different methods, and thermodynamic functions were derived from spectroscopic data for the temperature range 200–2000 K. Earlier investigations of these molecular constants were less accurate or incorrect.

The anharmonic force constants and electric dipole fields of NF_3 can be predicted from *ab initio* computations [196].

Much has been written about the difference in basicity and proton affinity of ammonia NH_3 versus nitrogen trifluoride NF_3 . Nitrogen trifluoride is not a base and has a very low, if any, proton affinity. Ion cyclotron resonance has been used to detect even traces of proton affinity of NF_3 in the gas phase [197].

1.2.14 Dipole Moment of Nitrogen Trifluoride

Nitrogen trifluoride is non-basic with a low dipole moment of 0.2340 D. By contrast, ammonia is basic and highly polar (1.47 D). The dipole moment of NF_3 is lower than the dipole moment of NH_3 , which can be explained by the reversed polarity of nitrogen. This difference arises from the fluorine atoms acting as electron-withdrawing groups, attracting essentially all of the lone-pair electrons on the nitrogen atom and reducing

its basicity. NF_3 has a positively polarized nitrogen atom, and the dipole moment of the lone pair is in the opposite direction to the dipole moment along the same axis associated with the three N—F bonds. In ammonia, the polarities are reversed, and the moments due to the N—H bonds and the lone pair operate in the same direction. The intrinsic moment of the N—F bond in NF_3 is 1.24 or 1.60 D, whereas it is 1.29 D in N_2F_4 [198].

When calculating the dipole moment of NF_3 , some investigators have neglected to consider the ionic character of the N—F bond. The bond may have 42% ionic character [199].

1.3 Chemical Properties of Nitrogen Trifluoride

Compared to the other nitrogen halogenides NCl_3 and NI_3 , which explode at the slightest stimulus, NF_3 is remarkably stable. Accidents have happened during the production of NF_3 when unstable by-products accumulated in cold traps, but these accidents were later blamed on unstable intermediates [28]. Contrary to the reactivity of fluorine or oxygen fluoride, NF_3 does not react with water at room temperature. It is somewhat soluble in water. It does not react with dilute caustic or acids, it does not hydrolyze, and it does not form salts in aqueous solutions as ammonia does (but it will form NF_4^+ salts with strong Lewis acids in anhydrous hydrogen fluoride).

Although initial thermodynamic and molecular orbital calculations let the stability of NF_4^+ salts appear unlikely [200, 201], skilled experimenters did succeed in synthesizing several NF_4^+ salts that might even be useful as oxidizers in solid rocket propellants or chemical lasers.

Nitrogen trifluoride is resistant to chemical attack by water and aqueous acids. The compound can be recovered quantitatively after 1 week in contact with excess dilute acid (HNO_3 , H_2SO_4 , HClO_4) or water at 406 K (133 °C) [202, 203]. In the presence of aqueous base, however, slow hydrolysis occurs at 373 K (100 °C). When boiled with hot caustic above 373 K (100 °C), NF_3 eventually hydrolyzes and decomposes to nitrite and fluoride. The unstable HONF_2 may be an intermediate in the hydrolysis. This differs from the hydrolysis of nitrogen trichloride, which gives ammonia and hypochlorite under similar conditions. While NF_3 is stable toward aqueous HCl, it reacts readily with hot, neutral sodium chloride solutions. The active species is the Cl^- anion, not the OH^- anion.

Mixtures of NF_3 and water steam can be made to burn in a slow flame reaction

when ignited by an electric spark. Mixtures of NF_3 with combustible gases such as NH_3 , H_2 , CH_4 , C_2H_4 , CO , or H_2S combust explosively when ignited by a flame or

a capacitor discharge over a spark gap. Alkali metals as well as zinc, boron, and arsenic will ignite when heated in NF_3 . Copper and silver react only superficially with NF_3 at $\sim 600\text{--}800\text{ K}$ ($\sim 350\text{--}550\text{ K}$). Reactions of NF_3 with metals often lead to N_2F_4 as the reaction product [204].

It is known that the reaction of NF_3 with metal wire in a flash bulb produces a very bright light, suitable for flash photography. The reaction of NF_3 with other metals has been studied as well [205].

Unlike NH_3 , NF_3 does not react with diborane. The basicity of NF_3 is much lower than that of NH_3 .

In order to study the hydrolysis of NF_3 , a 300-mL borosilicate glass bulb was evacuated and filled with 23 mL of water and 0.40 g of NF_3 . The bulb was then heated to 373 K (100°C) and held at that temperature for 7 d. The partial pressure of NF_3 at that temperature was calculated to be 470 mm Hg. The reaction was assumed to be

The amount of acid that was formed was found by titration with sodium hydroxide. The percentage of nitrogen trifluoride that had reacted was calculated on the basis of this equation and was 1.5% [35]. Additional information on chemical properties of NF_3 and other nitrogen fluorides can be found in [10, 11, 206].

1.3.1 Thermal Decomposition of Nitrogen Trifluoride

It appears that most experiments on the thermal decomposition of NF_3 were done in shock tubes, often in parallel with studies of the dissociation of N_2F_4 , which also leads to the relatively stable $\bullet\text{NF}_2$ free radical. It is probably difficult to study the homogeneous thermal decomposition of NF_3 gas by conventional methods in a static reactor or in a flow reactor because the gas would attack the walls and destroy the apparatus.

The rate of dissociation of nitrogen trifluoride in excess argon has been determined by measuring the rate of formation of $\bullet\text{NF}_2$ in the temperature range 1050–1390 K using a shock tube coupled with a spectrophotometric analysis technique [207]. In the range of 0.273–0.606 MPa (2.7–6.0 atm) total pressure, the reaction was found to be first order in both NF_3 and Ar concentrations. The reaction may be represented by

where M is a third-body gas. and for small conversions, other reactions were shown to be unimportant. The temperature dependence of the bimolecular rate constants can be described by

$$k = 10^{10.10 \pm 0.002} \exp\left(\frac{E_a}{RT}\right)$$

where E_a is the activation energy of -126 ± 9.6 kJ/mol (-30.1 ± 2.3 kcal/mol), k is the rate constant in $\text{mol}^{-1} \text{s}^{-1}$, and T is the temperature in kelvin. It was noted that the apparent activation energy is significantly lower than the bond dissociation energy, $D(\text{NF}_2-\text{F})$.

The proposed use of NF_3 and N_2F_4 as reagents in premixed HF or DF chemical lasers or rare gas halide excimer laser systems is one of the reasons why the dissociation of NF_3 and N_2F_4 has been investigated, as well as in combination with rapid thermal reactions of these substances with H_2 . Although flames of NF_3 and H_2 have been reported, these gases may be pre-mixed up to 373 K (100 °C) without reaction. In contrast, $\text{N}_2\text{F}_4/\text{H}_2$ mixtures without an inhibitor are spontaneously explosive near room temperature. Measurement of the UV absorption by $\bullet\text{NF}_2$ near 260 nm is the commonly used analytical method.

Shock waves in gas mixtures containing >94% Ar were combined with time-resolved spectrometry of $\bullet\text{NF}_2$ absorption at 260 nm and HF emission at $2.7\mu\text{m}$ in a study of rapid thermal reactions of NF_3 and mixtures of H_2 with NF_3 or N_2F_4 [208]. NF_3 decomposition between 1100 and 1500 K produced maximum $\bullet\text{NF}_2$ concentrations accountable by the equilibrium

followed by slower, irreversible $\bullet\text{NF}_2$ removal. NF_3/H_2 mixtures were inert for 2.2 ms below 1000 K and reacted in 550 ps above 1500 K, exhibiting complete HF yield, preceded by IR emission, no resolvable $[\text{NF}_2]$ transient, and copious $\text{NH}(\text{A}^3\Pi - \text{X}^3\Sigma^-)$ chemiluminescence at 336 nm during the reaction. Delayed and dynamically unstable gas reactions occurred over the $1000 < T < 1500$ K range. Pyrolytic dissociation and subsequent bimolecular reactions of the intermediates in the mechanism of stoichiometric formation of HF and N_2 may play a role in this process. Early attempts to observe 260-nm absorption during the $\text{NF}_3 + \text{H}_2$ reaction revealed instead the presence of strong UV chemiluminescent emission. Some of the tests required an inhibitor such as butene-1 to prevent premature ignition. This study was done in support of the planned use of $\text{N}_2\text{F}_4/\text{H}_2$ mixtures in lasers.

The thermal decomposition of NF_3 was reinvestigated behind incident shock waves in dilute (1%) NF_3/Ar mixtures over the temperature range 1150–1530 K and at 80.8–183 kPa (0.80–1.81 atm) total pressure, monitoring $\bullet\text{NF}_2$ radical concentrations in UV absorption at 260 nm or IR emission at $5.17\mu\text{m}$ [209]. The low-pressure-limit second-order rate constant was found to be

$$k_1 = 10^{16.61} \pm 0.13 \exp\left(\frac{E_a}{RT}\right)$$

where k_1 is the rate constant in $\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}$, E_a is the activation energy $E_a = -201 \pm 3.3$ kJ/mol (-48.0 ± 0.8 kcal/mol), and T is the temperature in kelvin.

Although different investigators agreed that the dissociation reaction is unimolecular, there was still a considerable spread in the activation energy and Arrhenius rate parameter proposed for this reaction.

The decomposition of 0.25, 0.5, and 1.0% NF_3 in argon was studied in a reflected shock wave [210]. In these dilute mixtures, the unimolecular decomposition pathway could be studied independently of other modes of decomposition. The temperature range of the study was 1500–2400 K, and the total pressure range was 0.8–60 atm. The total gas concentration behind the reflected shock ranged from 5×10^{-6} to 3.6×10^{-4} mol/cm³. Kinetic measurements were made by following the decay of emission of the $\nu_3 + \nu_1$ combination band of NF_3 at 5.18 μm . The unimolecular rate constants were obtained from the emission decay data and were converted to second-order rate constants by dividing by the total gas concentration. The Arrhenius parameters calculated by a least-squares analysis of the second-order rate constants were given as

$$k = 10^{14.7} \exp\left(-\frac{56300}{RT}\right)$$

where k is the second-order rate constant in cm³ mol⁻¹ s⁻¹ and T is the temperature in kelvin. The activation energy for the reaction was very close to the first N–F bond energy of 238 kJ/mol (57 kcal/mol). The results suggested that under the reported conditions, vibrational equilibrium was not maintained during the shock-wave reaction.

Repeating some of the measurements with both IR emission at 5.18 μ and UV absorption at 270 m μ to analyze the $\bullet\text{NF}_2$ concentration, a rate constant of 2.5×10^4 s⁻¹ was derived from the IR emissions curve [211].

The kinetics of thermal dissociation of NF_3 in argon has been studied over the temperature range between 1461 and 2026 K using shock-tube heating [212]. The rate of formation of the reaction product NF_2 was monitored by following the absorption of a characteristic NF_2 band at 2600 Å. The total sample pressure of the experiment was between 0.98 and 1.47 atm, and the NF_3 concentration in Ar was between 1 and 5%. The reaction was found to be first order in both NF_3 and Ar and may be represented by

The second-order rate expression was found to be

$$k_{\text{Ar}} = 10^{(10.02 \pm 0.06)} \exp\left(-25.7 \pm 0.6 \frac{\text{kcal}}{RT}\right) \text{mol}^{-1} \text{s}^{-1}$$

The thermal dissociation rate of NF_3 in mixtures of 5 and 10% NF_3 in Ar has been measured behind incident shock waves over the temperature range 1330–2000 K [213]. Dissociation rates were determined from post-shock density gradients measured by laser beam deflection. The second-order rate coefficient determined for NF_3 -Ar collisions was $k = 2.31 \times 10^{15} \exp(-20500/T) \text{cm}^3 \text{mol}^{-1} \text{s}^{-1}$.

Dissociation is always limited by the reverse reaction due to recombination, which might limit the laser light output. The recombination reaction

has been investigated experimentally in electron beam-excited Ne/Xe/NF₃ mixtures [214]. The results obtained were in excellent agreement with theoretical predictions from knowledge of the dissociation forward reaction.

Prior to dissociating, the NF₃ molecule rotates and vibrates internally as it is being heated. It may also lose an electron and become an ion, which has a different lifetime than the parent molecule. The excited states of NF₃ and NF₃⁺ as a function of their initial internal-energy state have been studied by a photoelectron-photoion coincidence technique [215]. The fragments, products of dissociation, may leave in excited states and lase.

The rate constant of NF₃ dissociation in a helium mixture near the low-pressure limit was directly measured in a shock tube by a UV absorption method in the temperature range 1050–1600 K [216, 217]. The rate constant in the temperature range $T = 1050\text{--}1600\text{ K}$ may be expressed as

$$k = 10^{14.38 \pm 0.07} \exp\left(\frac{E_a}{RT}\right)$$

where k is the rate constant in $\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}$, E_a is the activation energy $E_a = -153 \pm 8.8 \text{ kJ/mol}$ ($-36.6 \pm 2.1 \text{ kcal/mol}$), and T is the temperature in kelvin. Levels of the NF₃ stationary dissociation fraction were also measured as a function of the initial temperature of the mixture behind the shock wave. It increased monotonically with temperature and reached 50% of the value at 1600 K, which corresponded to high $\bullet\text{NF}_2$ concentrations of up to $2 \times 10^{17} \text{ cm}^{-3}$. Rates of NF₃ thermal decomposition in the temperature range 1950–2050 K and pressure range 1.2–4.2 atm were also measured. The bimolecular rate constant of the NF₃ decomposition reaction depended strongly on the pressure.

Rates of NF₃ thermal decomposition in the temperature range 1450–2050 K and pressure range 121–424 kPa (1.2–4.2 atm) were measured by a shock-tube technique [218]. NF₃ decomposition was monitored by UV absorption of the produced $\bullet\text{NF}_2$ radicals. The bimolecular rate constant of the NF₃ decomposition reaction depends on the pressure. An empirical formula was obtained from the experimental data that correctly expressed the dependence of the measured rate constant of decomposition upon the temperature and pressure of the reacting mixture behind the shock wave.

NF₃ that is used for etching silicon wafers or for cleaning CVD equipment has to be pre-dissociated in a plasma discharge, creating atomic fluorine free radicals. A radiofrequency (RF) plasma system can be used for decomposing NF₃. NF₃ was almost completely decomposed (>99%) at an input power of 30 W. However, allowing traces of O₂ to the system inhibited NF₃ decomposition [219]. The products detected in the NF₃/O₂/Ar plasma system were NO₂, NO, N₂O, SiF₄, N₂, and F₂.

Plasma excitation of NF_3 is not only useful for silicon etching and CVD equipment cleaning but, with the addition of some hydrogen gas as a reductant, can also be used for the destruction of unwanted NF_3 waste gases venting from other industrial processes. Low-power arc plasma discharges are characterized by extremely high enthalpy and temperature and are easy to generate and control, so thermal decomposition processes based on the plasma torch are receiving a lot of attention for decomposing non-degradable greenhouse gases. The effects of input power, waste gas flow rate, and additive gases on the destruction and removal efficiency of NF_3 have been examined [220]. Specific energy density decreased as the flow rate increased, and, accordingly, the destruction efficiency was reduced. The destruction efficiency is determined by the specific energy density. The highest destruction efficiency of NF_3 was 97% for a waste gas flow rate of 100 L/min at a low input power level of 2 kW with the help of hydrogen additional gas. The inlet and outlet concentration of NF_3 was analyzed using FTIR. See also [221].

1.3.2 Catalytic Decomposition of Nitrogen Trifluoride

Catalytic decomposition of nitrogen fluoride would facilitate the disposal of surplus NF_3 from industrial processes now that these gases may no longer be vented to the atmosphere. The NF_3 decomposition products would be more reactive than NF_3 itself and would then be easier to remove by reaction with a caustic washing fluid and calcium chloride.

The decomposition of NF_3 in the absence of water over Al_2O_3 , Fe_2O_3 , Co_3O_4 , and NiO and transition metal oxide (Fe_2O_3 , Co_3O_4 , and NiO)–coated Al_2O_3 reagents was investigated [222, 223]. The results showed that Al_2O_3 is an active reagent for NF_3 decomposition, with 100% conversion lasting for 8.5 h at 400 °C. Fe_2O_3 , Co_3O_4 , and NiO -coated Al_2O_3 reagents were superior to bare Al_2O_3 , and 5% $\text{Co}_3\text{O}_4/\text{Al}_2\text{O}_3$ had a high reactivity, with NF_3 full conversion maintained for 10.5 h.

1.3.3 Photolysis of Nitrogen Trifluoride

It was hoped that photolysis of NF_3 or N_2F_4 in the presence of an excess of fluorine would produce higher fluorides of nitrogen ($\text{NF}_5?$), but that has not yet been shown. The other reason that the photolysis of NF_3 was studied in detail is that NF_3 may be used as a source of fluorine atoms in chemical lasers with D_2 .

One method to study the strength of chemical bonds is to attempt to break them by photolysis at different wavelength of light, using shorter and shorter wavelength until some dissociation is observed. Photolysis of NF_3 or N_2F_4 forms $\bullet\text{NF}_2$ free radicals that are comparatively long-lived [224].

Irradiation of an equilibrium mixture of N_2F_4 and $\bullet\text{NF}_2$ at room temperature gave NF_3 and N_2F_2 , along with N_2 and other products involving N_2F_2 decomposition products [225]. Coupling of fluoronitrene NF can give rise to N_2F_2 , a reaction that other ni-

trenes undergo, and $\bullet\text{F}_2$ and $\bullet\text{NF}_2$ may combine to make NF_3 . Photolyzed NF_3 or N_2F_4 can enter into all kinds of new reactions that would not take place in the dark [226].

With the rapid growth of the semiconductor and thin-film liquid crystal display manufacturing industries, large quantities of the potent greenhouse gas NF_3 are used and are accidentally or negligently leaked to the atmosphere. Similar to perfluorocarbons, NF_3 is very stable because of its molecular structure. Therefore, in the atmosphere on Earth, NF_3 is difficult to oxidize by O_3 , NO , NO_2 , or OH radicals, except by excited oxygen atoms $\text{O}(^1\Delta)$ that can react with it to form NF_2 or other products. In the upper atmosphere, anthropogenic NF_3 is a suspected greenhouse gas and ozone-layer depletion agent similar to CF_4 and SF_6 . The photolysis reactions of NF_3 in the upper atmosphere under the influence of UV light from the sun have therefore been investigated.

If the wavelength of UV radiation is varied, coming from the long-wavelength end of the spectrum until first ionization is detected, the photolysis/mass spectrometry method can be used to determine the bond strengths of the bonds being broken. Photoionization yield curves for the NF_3^+ , NF_2^+ , and NF^+ ions of NF_3 were measured from the threshold to 600 Å [227]. The ionization energies were used to calculate heats of formation of the ions, ionization energies of radicals, and bond dissociation energies. For NF_3 , the bond dissociation energies were $D(\text{NF}_2-\text{F}) = 2.39 \text{ eV}$, $D(\text{NF}-\text{F}) = 3.4 \text{ eV}$ and $D(\text{N}-\text{F}) = 2.4 \text{ eV}$.

The UV photodissociation of NF_3 and NF_2 has been investigated from 240–270 nm, using tunable UV radiation from a frequency upconverted YAG pumped dye laser system [228]. The absorption cross-section of NF_2 and the photolysis quantum yield for the fragment $\text{NF}(a^1\Delta)$ were measured with 0.25-cm^{-1} resolution. The $\text{NF}(a^1\Delta)$ quantum yield decreased at longer wavelengths and was only 1% at 260 nm. This suggested that the first long-wavelength band in NF_2 leads primarily to ground state $\text{NF}(X^3\Sigma)$ and that the existence of a new, higher-lying NF_2 electronic state is responsible for the $\text{NF}(a^1\Delta)$ production.

Nitrogen trifluoride was found to be stable toward photo-oxidation reactions that limit the atmospheric lifetimes of many detrimental gaseous species. Reactions with species such as $\bullet\text{OH}$ and $\bullet\text{OOH}$ are thermodynamically unfavorable. The reaction with O_3 , while thermodynamically favorable, was found to be too slow to be of atmospheric importance [229]. Measurements of the NF_3 absorption cross-sections from 180 to 250 nm yielded values that were smaller than those previously reported and indicated an atmospheric lifetime against photodissociation in the stratosphere of about 700 years. In addition, the IR band strengths were determined in order to enable estimates of greenhouse-warming potentials.

Although NF_3 , a trace gas of purely anthropogenic origin with a large global-warming potential, is accumulating in the Earth's atmosphere, little photochemical data existed from which to calculate its atmospheric removal rate. Photodissociation quantum yields, Φ_1 , were derived following 193.3-nm laser photolysis of NF_3 and

quantitative conversion of the F-atom photoproducts to OH, which was detected by laser-induced fluorescence [230]. Values of $\Phi_1(P,T) = (1.03 \pm 0.05)$ were determined at pressures between 28 and 100 mbar of He or N₂ and at either room temperature or 255 K. Absorption cross-sections, σ , obtained between 184 and 226 nm were combined with the values of $\Phi_1(P,T)$ to confirm a long (~700-year) photolysis lifetime for NF₃. No evidence for reaction of OH with NF₃ was found, indicating that this process makes little or no contribution to NF₃ removal from the atmosphere. These results underpin recent calculations of an NF₃ atmospheric lifetime of $\tau \sim 550$ years, largely controlled by photolysis in the stratosphere.

Photochemical processes were evaluated for the destruction of unwanted NF₃ in the waste gases from industrial processes at 5 mm Hg partial pressure of NF₃ and 600 mm Hg total pressure, with buffer gas of argon in a reactor based on controlled release of radicals [231]. The results indicated that reductive double bonds and allyl radicals, slowly released from polyisoprene irradiated by a UV lamp emitting 185 and 253.7 nm of light, could achieve NF₃ degradation. The NF₃ degradation efficiency was significantly affected by O₂ and was almost independent of N₂ and reached 96% with a kinetic rate constant $k \sim 1.77 \times 10^{-4} \text{ s}^{-1}$ after 300 min of UV irradiation.

1.3.4 Radiolysis of Nitrogen Trifluoride

The main industrial use of NF₃ is in silicon etching and cleaning of CVD equipment in the semiconductor industry. In these applications, NF₃ has to be activated by passing it through a glow discharge before directing the molecular beam at the surface to be cleaned or eroded. In a glow discharge, a stream of fast electrons knocks one or two atoms out of the NF₃ molecule. Ionization of NF₃ by fast electrons also takes place in the inlet of mass spectrometers and in the high atmosphere (where NF₃ is an unwanted contaminant). In the synthesis of tetrafluoroammonium salts, NF₃ and the other reactants are passed through a glow discharge and are excited so that they will perform reactions that cannot take place at room temperature in the absence of an electron beam. Fast electrons are sometimes called β -radiation.

Low-energy electron impact on NF₃ caused continuous UV emissions in the range of 2000–3400 Å [232]. It produced a structured emission with maxima at 2880, 3005, and 3130 Å and an onset energy of $8.5 \pm 2 \text{ eV}$ superimposed on a continuous feature from 2500 to 3500 Å with an onset at about 30 eV, which has been attributed to the NF₂ fragment. UV emission can be used to monitor the proper operation of semiconductor etching equipment.

Depending on the accelerating voltage, the electron beam may knock off one or two fluorine atoms from the NF₃ molecule. In the latter case, the NF²⁺ ion is formed once its appearance energy ($43.8 \pm 1.0 \text{ eV}$) in the electron impact ionization of NF₃ is exceeded [233].

The absolute cross-sections for the electron-impact ionization of NF₃ from threshold to 200 eV were obtained independently in two different laboratories using two

different experimental techniques, and the agreement was better than $\pm 8\%$ [234]. At 70 eV, the absolute parent NF_3 ionization cross-section was $0.35 \pm 0.06 \text{ \AA}^2$. Absolute cross-sections for the formation of the fragment ions NF^{2+} and NF^+ were found to be, respectively, 1.05 ± 0.20 and $0.7 \pm 0.15 \text{ \AA}^2$ NF^+ at 70 eV.

Close-coupling calculations were made for low-energy electron-collision processes involving NF_3 to obtain cross-sections for (dissociative) excitation of the lowest singlet and triplet electronically excited states [235].

Absolute elastic cross-sections for electron impact on NF_3 have been measured for impact energies from 1.5 to 100 eV and scattering angles from 20 to 130° [236]. Vibrational excitation function measurements showed a 2-eV-wide resonance at 3-eV impact energy. Vibrational loss spectra were measured near this resonance and were resolved into their vibrational components.

The electron collision cross-section of NF_3 is of interest for modeling plasma-enhanced etching of materials. Measurements of the absolute dissociative ionization cross-sections of NF_3 were compared with previous data in the literature for electron attachment, momentum transfer, vibrational excitation, and dissociative excitation [237].

The partial cross-sections creating NF_x^+ ($x = 0, 1, 2, 3$), F^+ and NF_x^{2+} ($x = 1, 2, 3$) during the ionization and dissociative ionization of NF_3 by electron impact were measured by Fourier transform mass spectrometry [238]. The total ionization cross-section grew to a maximum value at 140 eV. Estimates of the total single ionization cross-section using *ab initio* energies with the binary encounter models were roughly twice the measured values.

Absolute total cross sections for 0.5–370-eV electrons scattered by NF_3 molecules have been measured employing the transmission method in a linear configuration [239]. It was found that the total cross-section energy function for NF_3 is dominated by two pronounced enhancements: one resonant-like centered between 2 and 3 eV with the maximum value of $28 \times 10^{-20} \text{ m}^2$ followed by a minimum at around 7–12 eV, $17 \times 10^{-20} \text{ m}^2$, and the second much broader enhancement located around 40 eV ($19 \times 10^{-20} \text{ m}^2$ in the maximum). The maximum, resonant in character, is centered between 2.2 and 3 eV and is superimposed with weak features located at 1.8, 2.2, and 2.8 eV. With low-energy (“thermal”) electrons, one ionization step might be a simple electron attachment, forming NF_3^- ions. The rate constant for the dissociative attachment of thermal electrons (300–350 K) to NF_3 has been measured using a flowing afterglow technique [240].

Total cross-sections of electron impact scattering by NF_3 molecules were measured over electron impact energies from 1 eV to 5 keV and compared to predicted values from *ab initio* calculations [241]. Electronic excitation, rotational excitation, and differential cross-sections were calculated at low incident energies. Resonances were detected at 5.6 and 6.2 eV, indicating the probability of anion formation by the electron attachment process and further decay to neutral and negative ion fragments.

Gamma irradiation of NF_4AsF_6 has created trapped $\bullet\text{NF}_3^+$ free radicals that have a trigonal pyramid structure and could be identified by electron paramagnetic resonance (EPR) [242].

Exposure of liquid NF_3 at 77, 100, or 134 K to intense X-ray radiation from a 3-MeV X-ray source with dose rates up to 100 Mrad/h resulted in the formation of a mixture of N_2 , F_2 , *cis*- N_2F_2 , and *trans*- N_2F_2 and very little N_2F_4 [243, 244]. No higher fluorides of nitrogen (NF_5 ??) were detected.

1.3.5 Decomposition of Nitrogen Trifluoride in a Glow Discharge

In an attempt to synthesize higher (higher than N(III)) fluorides of nitrogen, nitrogen trifluoride was mixed with fluorine and other gases and subjected to a glow discharge [101]. Instead of forming a higher nitrogen fluoride like NF_5 , NF_3 decomposed in the glow discharge into its elements. Additions of F_2 , N_2 , or O_2 had little effect on the decomposition [245]. Fluorine slowed down the decomposition of nitrogen trifluoride, whereas nitrogen and oxygen accelerated it. Trifluoroamine oxide was obtained with a yield of ~15% from an equimolar mixture of nitrogen trifluoride with oxygen in a discharge tube, cooled with liquid nitrogen.

1.3.6 Reactions of Nitrogen Trifluoride with Inorganic Substances

The reaction of NF_3 with crystalline elemental boron was carried out in a bomb calorimeter, and the heat of reaction was measured [136]. The heat of reaction was $-1003 \text{ kJ/formula weight}$ ($-239.7 \pm 1.2 \text{ kcal/formula weight}$), and the heat of formation of gaseous NF_3 derived from this number was $-127.2 \pm 5.0 \text{ kJ/mol}$ ($-30.4 \pm 1.2 \text{ kcal/mol}$).

For a better understanding of the lifetime of NF_3 and the mechanisms for its destruction in the upper atmosphere, where it acts as a greenhouse gas, the mechanism of the reaction of NF_3 with atomic oxygen $\text{O}(^1\text{D})$ has been thoroughly investigated.

The reactions of $\text{O}(^1\text{D})$ atoms with NF_3 were investigated by time-resolved laser magnetic resonance [246]. $\text{O}(^1\text{D})$ atoms were produced by the dissociation of ozone with an excimer laser (KrF, 248 nm). $\text{O}(^1\text{D})$ reacts with NF_3 by two competitive processes:

The rate constant for total removal of $\text{O}(^1\text{D})$ by NF_3 at 298 K was $(1.2 \pm 0.25 \times 10^{-11} \text{ cm}^3/\text{s})$, and the reaction rate constant for NF_3 was $(1.0 \pm 0.3 \times 10^{-11} \text{ cm}^3/\text{s})$. It was attempted to back up these experiments by theoretical computations [247, 248].

Absorption of infrared radiation from a continuous wave (CW) CO_2 laser in nitrogen fluorides initiated a number of reactions between NF_3 or N_2F_4 and nitric oxide (NO), nitrous oxide (N_2O), nitrogen dioxide (NO_2), or nitrosyl chloride (ClNO) [249]. In all cases, the major product was FNO , and when N_2O or NO_2 was used, some FNO_2

was also produced. No higher states of oxidation of nitrogen were detected. The laser-induced reactions probably proceeded through a non-equilibrium thermal process rather than a true multi-photon dissociation, but some data were not totally consistent with this interpretation.

The crystal structures of protective films of FeF_2 and NiF_2 formed on Fe and Ni surfaces in NF_3 and SF_6 at 1473 K (750 °C) were examined by electron diffraction [250]. In NF_3 at 473–573 K (200–300 °C), a phase transformation of $\text{FeF}_2 \rightarrow \text{FeF}_3$ was observed.

The reaction of NF_3 with metal powders was evaluated as a method to remove NF_3 trace from process gases. Of the three metals (Ti, Si, Sn) evaluated as NF_3 -getters, Ti powder performed best. The reaction of NF_3 with Ti started at 433 K (160 °C), and the conversion was 99.8% when the metal was heated to 598 K (325 °C) [251].

That NH_3 forms a hydrate with water has been long known, but that NF_3 can also form a clathrate hydrate with a P_{m3n} cubic unit cell dimension of 11.91 Å at 110 K came as a surprise [252]. NF_3 hydrate samples were prepared by condensing NF_3 at low temperatures into a pressure vessel containing degassed H_2O or D_2O ice and several stainless steel rods and allowing NF_3 and water to react. During the reaction period, the pressure vessel was rolled so as to subject the solid sample to continuous grinding. Hydrate formation was monitored by the decrease in gas pressure, which was normally complete in 24 h. The dissociation pressure of NF_3 hydrate was 16.5 ± 0.2 atm at 273 K (0 °C) and 3.7 ± 0.2 atm at 233 K (–40 °C). This hydrate is therefore more stable than the hydrates of CH_4 or CF_4 , whose dissociation pressures at 273 K (0 °C) are 26.0 and 41.5 atm, respectively.

Fluorine reacts with most other compounds spontaneously at room temperature, and those that do not sometimes need a little help in the form of an electric discharge or UV illumination or high temperature and high pressure. This may lead to compounds in higher states of oxidation, but in the case of NF_3 it did not work for the synthesis of NF_5 [253, 254].

One of the main applications of NF_3 , and one of the main reasons why there is now such a high demand for NF_3 , is the deep reactive ion etching of silicon wafers in the production of semiconductors and masks for color television displays. The NF_3 is activated in a plasma discharge in an ion gun, and as it impinges on the solid elemental silicon, it forms SiF_4 gas, which is carried away with the carrier gas. The reactions of NF_3 with Si and SiC have been studied using X-ray photoelectron spectroscopy–electron spectroscopy for chemical analysis (XPS-ESCA) [255]. This was done to study and differentiate the role of ions and neutrals in NF_3 plasma etching of Si. Both ion-beam and plasma experiments indicated that etching, nitridation, and fluorination of Si occurred simultaneously. Density functional theory (DFT) calculations were performed to test the validity of the qualitative electronegativity approach in interpreting the XPS results [256]. The DFT calculations confirmed the expected changes in atomic charge and the direction of binding energy shift for $\text{F}\bullet\text{N}\bullet\text{Si}$ moieties.

The effects of rf power and NF_3 pressure on the etching rate of SiC and the surface morphology were investigated by means of scanning electron microscopy (SEM) and

atomic force microscopy [26]. A procedure for getting a smooth and residue-free etched surface of SiC with a high etching rate of 87 nm/min was developed under the conditions such as rf power of 100 W and NF_3 pressure ranging from 0.5 to 1 Pa. A smooth surface within the scale of ~ 300 nm can be obtained.

1.3.7 Reactions of Nitrogen Trifluoride with Organic Substances

Nitrogen trifluoride is not nearly as reactive as tetrafluorohydrazine when one is looking for a method to prepare organic difluoroamino compounds. It can be used as an additive in the hydrofluorination reactions of chlorocarbons with anhydrous hydrogen fluoride and chromium catalysts [257]. Nitrogen trifluoride does not add to the double bond in olefins as readily as N_2F_4 does. Perfluoroalkyldifluoroamines can be made from perfluoroolefins (hexafluoropropene or tetrafluoroethylene) and NF_3 in moderate yields [258]. Sometimes the reacting mixtures of NF_3 and organic compounds that one intends to fluorinate ignite prematurely.

1.3.8 Analytical Methods

1.3.8.1 Analysis of Nitrogen Trifluoride Traces in Air

With increasing industrial use of NF_3 , there is a need for automated monitoring of workroom air in semiconductor processing facilities. The threshold limit value (TLV)–maximum allowable concentration (MAC) of NF_3 was established by the American Conference of Governmental Industrial Hygienists (ACGIH) in 1993–1994 as 10 ppm (29 mg/m^3) time-weighted average (TWA), so the instruments have to be sensitive to at least that level in air.

In order to test the sensitivity of NF_3 detection by IR, an existing IR monitor intended for the detection of Otto Fuel II was modified for use in the 900-cm^{-1} region [259]. The optical path length was 17.2 m by multiple reflection. There was strong interference by HNO_3 and several other vapors. The instrument was capable of detecting down to 1 ppm NF_3 in air.

Other than the occupational hygiene concern about the presence of NF_3 in parts-per-million levels in workroom air, there is concern about the environmental impact of NF_3 in the atmosphere. Highly sensitive methods have been developed to analyze NF_3 in ambient air and are sensitive down to the parts-per-trillion level. There is no natural source for NF_3 , so all NF_3 in the atmosphere is man-made (“anthropogenic”). A preconcentration gas chromatography/mass spectrometry (GC/MS) technique of gas separation and chromatography after initial preconcentration was used to conduct *in situ* measurements of NF_3 in the air above La Jolla, California, and as of December 2011, NF_3 measurements ranged from ~ 0.85 to 1.18 ppt, with a gradual rise in the baseline concentration [260]. NF_3 and CF_4 were separated from more abundant gases before detection by the mass spectrometer. In the mass spectrometer, CF_4 was identified at $m/e = 69^+$, and NF_3 was identified at $m/e = 52^+$.

1.3.8.2 Analysis of Contaminants in Nitrogen Trifluoride

Nitrogen trifluoride, in accordance with the military specifications listed in Table 11, must be analyzed to verify the purity of the chemical because contaminants might interfere with operation of a chemical laser.

1.3.8.3 Military Specification for Nitrogen Trifluoride

The military specification for nitrogen trifluoride was issued for NF_3 intended as a chemical laser propellant. The specification has gone through several revisions over the past several decades (Table 11).

The military-specification purity requirements for NF_3 are listed in Table 12.

Total reactive fluoride is determined by slowly bubbling 4.5 L of NF_3 through 40 mL of 0.1-N NaOH in an impinger and analyzing the solution for fluoride with an ion-selective electrode.

Table 11: Military specifications for nitrogen trifluoride.

Designation	Date
MIL-P-87896	Oct 1982
MIL-P-87896 Amendment-1	Oct 1987
MIL-P-87896 Notice 1	Dec 1997
MIL-P-87896 Notice 2	Oct 2005
MIL-PRF-87896A	Jan 2011

Table 12: Purity requirements for nitrogen trifluoride according to military specifications.

Composition	Limit per MIL-P-87896	Limit per MIL-P-87896, Amendment 1	Limit per MIL-PRF-87896A
Assay, (purity), nitrogen trifluoride (NF_3), %-vol, min	98.0	98.0	99.0
Tetrafluoromethane (CF_4), %-vol, max	1.0	1.0	0.5
Carbon monoxide (CO) + oxygen (O_2) + nitrogen (N_2), %-vol, max	0.5	1.5	—
Oxygen + argon, %-vol, max	—	—	0.1
Carbon monoxide (CO), %-vol, max	—	—	0.1
Carbon dioxide (CO_2), %-vol, max	0.1	0.1	0.1
Nitrogen	—	—	0.1
Nitrous oxide (N_2O), %-vol, max	0.2	0.2	0.1
Sulfur hexafluoride (SF_6), %-vol, max	—	—	0.1
Difluorodiazine (N_2F_2), percent by vol, max	0.1	0.1	—
Total reactive fluoride (as HF, hydrogen fluoride), ppm by vol, max	0.1	10	1000
Water (H_2O), ppm by vol, max	5	5	5

1.3.8.4 Analysis of Nitrogen Trifluoride by Gas Chromatography

Mixtures of NF_3 with OF_2 , CF_4 , SiF_4 , N_2 , or O_2 can be analyzed by GC on a silica gel column that has been dried and desorbed by first heating to 1173 K (900 °C) and then coated with 30% halocarbon oil. They proved to be sufficiently resistant to very aggressive gases, while still giving good separations. The retention volumes of a series of inorganic gases on this column were measured, and the height equivalent of a theoretical plate (HETP) retention volumes were calculated [261].

The more difficult task is a complete separation of NF_3 from CF_4 because the boiling points of the two gases are nearly identical. Complete separation was achieved on a 12-m silica gel column cooled to 273 K (0 °C) as well as on a 3-m activated charcoal column cooled to 252 K (–21 °C) [55, 262]. Other gas chromatographic techniques for the separation of NF_3 from contaminants are described in [263, 264] and [265, 266].

In support of the development of a military propellant specification for NF_3 , a gas chromatographic analysis method was developed by the Air Force Research Laboratory (AFRL) [267, 268]. Because the specification represents the portion of a procurement contract that defines the quality of the product, it was necessary that all quality tests be reliable and, at the same time, as simple as possible so that a reproducible and high-quality product could be assured without unnecessarily high analytical costs for routine analysis. Nitrogen trifluoride is a relatively inert compound at ambient temperature; however, the possible impurities can vary from highly reactive (e.g., HF , F_2 , N_2F_4 , COF_2 , N_2F_2) to very inert (e.g., N_2 , O_2 , CF_4 , CO_2 , N_2O). Also, impurities of intermediate reactivity (e.g., NO , NO_2 , CO) can be present. Analysis of such a potentially complex mixture required some compromise with respect to specificity in order to maintain reasonable analysis costs. The impurities can be grouped into several categories: (1) those that lower performance by dilution, (2) those that lower performance by interference with the fuel/oxidizer reaction, and (3) those that affect the storability of the propellant. Active fluoride was determined by a wet chemistry method in which the gas sample was bubbled through 40 mL of 0.1N NaOH . A total active fluoride determination will provide a greater penalty for N_2F_4 contamination than for HF on a mol-for-mol basis. An active fluoride scrubber (4 in of 40/50 mesh KI followed by 4 in of 40/50 mesh $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$) was inserted between the gas source and the gas chromatograph to protect the instrument from corrosion. Nitrogen trifluoride was analyzed both with and without the active fluoride scrubber in place. Good separation was achieved with a 20-ft $\times$ 1/8-in-outer-diameter stainless steel column packed with 80/100 mesh Chromosorb 102 (Johns Manville) baked at 473 K (200 °C) and operated at 308 K (35 °C) with a thermoconductivity detector and helium carrier gas. This is the GC method adopted for MIL-P. The component elution order is H_2 , N_2 , $\text{CO}(\text{O}_2)$, NO , CF_4 , NF_3 , N_2F_2 , CO_2 , N_2O , and SF_6 . NO_2 may appear as a tailing peak between NO and CF_4 . A typical gas chromatogram with a real sample and a sample spiked with all contaminants is shown in Figure 3.

Figure 3: Gas chromatogram of NF₃ and a sample spiked with contaminants. (From MIL-P-87896.)

IR spectra were measured with a 100-mm path length micro gas cell with BaF₂ windows in an IR spectrophotometer. The outlet line of the gas valve was fed into an air/propane burner to destroy the excess NF₃. For IR analysis, poor sensitivity at the test conditions used will likely allow only NO₂, CF₄, and N₂O to be determined without scale expansion. GC fractograms and IR spectra were measured of a calibration mix with six contaminants at known concentrations and retention times and were compared to the analysis of a typical NF₃ sample (Figure 2 in Section 1.2.8.1).

A dual-column back-flush gas chromatograph was used to analyze impurities in NF₃ [269]. The impurities that were analyzed at the low mg/L levels included dioxygen (O₂), dinitrogen (N₂), carbon dioxide (CO₂), carbon monoxide (CO), sulfur hexafluoride (SF₆), methane (CH₄), and nitrous oxide (N₂O). Carbon tetrafluoride (CF₄) was also present in the product at levels of 20–400 mg/L. Good separation was achieved by using a dual-channel gas chromatograph with single-column back-flush switching on one channel for the determination of O₂, N₂, CH₄, and CO, with column-sequence reversal on a second channel for the determination of CO₂, N₂O, SF₆, and CF₄. A similar system using a combination of dual-column back flush and heart-cut configurations worked equally well. Pulsed-discharge helium ionization detectors were used on both channels in both configurations.

A dual-channel gas chromatographic method can be used for quantitation of NF_3/CF_4 mixtures with a thermal conductivity detector on one channel for the quantitation of high-concentrations and a pulsed-discharge helium ionization detector on a second channel for the quantitation of low concentrations [270]. It was shown that adequate separation can be achieved on both channels with this dual single-column setup in which column switching as used for NF_3/CF_4 analysis in industrial chromatographic methods is not required, thus yielding an effective analysis method for laboratory-scale investigations. The use of packed columns with purified divinylbenzene-styrene co-polymers as the sole stationary phase yields satisfactory resolution between NF_3 and CF_4 at isothermal conditions of 303 K (30 °C), with elution times of less than 8 min on the thermal conductivity detector (TCD) channel and less than 4 min on the pulsed-discharge helium ionization detector (PDHID) channel.

1.3.8.5 Analysis of Nitrogen Trifluoride by Mass Spectrometry

Electron impact ionization and dissociation of NF_3 in a mass spectrometer provided data on the relative abundances and appearance potentials of the NF_3^+ , NF_2^+ , NF^+ , N^+ , F^+ , F^- , and F_2^- ions [271]. The heat of formation of the NF_3 molecule can be used to determine the probable processes of formation of the N^+ and F^+ ions and to calculate the ionization potentials of the $|\text{NF}$ and $^*\text{NF}_2$ radicals.

Gases passing through the inlet of a mass spectrometer are usually ionized by electron bombardment, but they can also be ionized by UV radiation. If the wavelength of the UV radiation is varied, coming from the long-wavelength end of the spectrum until first ionization is detected, this photolysis/mass spectrometry method can be used to determine the bond strengths of the bonds being broken. Photoionization yield curves for the NF_3^+ , NF_2^+ , and NF^+ ions of NF_3 and the ONF_3^+ , ONF_2^+ , and NO^+ ions of NF_3O were measured from the threshold to 600 Å [227]. The ionization energies were used to calculate heats of formation of the ions, ionization energies of radicals, and bond dissociation energies. For NF_3 , the bond dissociation energies were $D(\text{NF}_2-\text{F}) = 2.39 \text{ eV}$, $D(\text{NF}-\text{F}) = 3.4 \text{ eV}$, and $D(\text{N}-\text{F}) = 2.4 \text{ eV}$.

1.4 Handling of Nitrogen Trifluoride

Nitrogen trifluoride was evaluated as the most promising near-term replacement for elemental difluorine F_2 in a DF chemical laser. Safety and compatibility characteristics of NF_3 have been scattered through the literature since the gas was first prepared by Ruff in 1928.

Summaries of the data to outline the general chemical behavior of NF_3 , critical safety, compatibility, and environmental were compiled in 1976 [259]. This was done as part of a System Safety Program Plan for the U.S. Department of Defense High En-

ergy Laser Program and included reactivity/materials compatibility, health effects, inhalation reactions, injection reactions, and effects on plants.

Guidelines for the safe handling of compressed gas nitrogen trifluoride are available from the Compressed Gas Association [272].

1.4.1 Disposal of Nitrogen Trifluoride

The disposal of nitrogen trifluoride waste gas has become a problem for the semiconductor and TV/computer display industry where NF_3 is used to etch masks and micro-machine silicone chips and to clean CVD equipment and remove unwanted deposits from the walls of the CVD chambers. In all of these applications it would be desirable not only to destroy the effluent NF_3 but to eventually capture, separate, purify, and recycle it, but that requires more effort. Surplus NF_3 can be disposed of by combustion with hydrogen, methane, propane, or butane in a caged flare stack, but then the HF combustion product needs to be washed out in a scrubber. Oddly enough, the chemical stability of NF_3 makes it more difficult to dispose of it through a chemical reaction. It does not dissolve in water and does not react quickly enough with water at room temperature. In all cases, one of the reaction products is HF, which needs to be scrubbed from the exhaust gas and then neutralized with lime or caustic.

The NF_3 concentration in effluents from semiconductor processing is much lower than NF_3 concentrations in pressurant gases vented from a liquid NF_3 tank following a rocket engine or laser test. The waste-gas treatment methods may be different but similar.

Metal oxides, manganese oxides, metals, and mixed systems were tested in the design of an effective, cost-efficient system with microwave heating to eliminate or recycle unreacted effluent NF_3 [273]. Interaction of microwaves and materials has proven to be an efficient method for material synthesis. Manganese oxides were chosen because they are known to absorb microwave radiation, indicating that synthesis of manganese oxides in a microwave field might lead to more efficient NF_3 absorbers.

The NF_3 can be recycled by passing the effluent gas mixture through a series of membrane separators, where the first membrane is more permeable to NF_3 and the second membrane is more permeable to the diluent gas at increased pressure, followed by pressure-swing adsorption, condensation, and fractionated distillation of the NF_3 [274].

A tandem packed-bed plasma and adsorbent hybrid gas cleanup system consisting of a BaTiO_3 packed-bed plasma reactor and a CaCO_3 adsorbent filter was used to study the removal of NF_3 from semiconductor-process effluent gases [275]. Plasma-chemical kinetics of $\text{N}_2/\text{NF}_3/\text{O}_2/\text{H}_2$ gas mixtures were studied to predict possible by-products. The laboratory-scale system demonstrated NF_3 removal at atmospheric pressure. Typically, 100% NF_3 abatement was achieved with an inlet concentration of 5000 ppm and a gas dwell time in the reactor of less than 10 s.

The CF_4 , C_2F_6 , or NF_3 waste gas used to be vented to the atmosphere, but environmental concerns about ozone-layer depletion and global warming now dictate a more controlled method of disposal [276].

Unwanted NF_3 waste gases venting from industrial processes can be destroyed by passing them through low-power arc plasma discharges with the addition of some hydrogen gas [220]. The destruction efficiency is determined by the specific energy density. The highest destruction efficiency of NF_3 was 97% for a waste-gas flow rate of 100 L/min at a low-input power level of 2 kW with the help of additional hydrogen gas.

1.5 Materials of Construction for NF_3 Systems

All materials that are found to be compatible with elemental fluorine can also be used for the design of NF_3 systems. NF_3 can be handled in glass apparatus and has even been used in flash bulbs.

A welding torch for welding refractory metals has been developed using NF_3 and H_2 , and several materials have been tested as candidates for this application because at the tip of the torch the temperatures are very high, similar to the injector of a rocket engine [277].

The chemical compatibility of nitrogen trifluoride was determined with 29 metallic materials and 22 non-metallic materials subjected to immersion tests [278]. Twelve types of tests were used in this determination: cleaning and passivation, static exposure, fracture mechanics/toughness, gaseous flow at high temperatures, adiabatic compression, water hammer, mechanical impact, liquid flow impact, screening, disposal, nitrogen trifluoride chemical analyses, and passivation film evaluation. Five common contaminants were included in the tests in order to determine their effect on chemical compatibility. Static exposure conditions ranged in temperature from 195 to 344 K and in pressure from 3.4 to 17.2 MPa. None of the metals tested exhibited corrosion penetration rates of greater than 1 mil (1/1000th of an inch) per year during a 270-d exposure period when exposed to the NF_3 . However, the presence of HF or H_2O enhanced the corrosion rates significantly. Of the non-metals investigated, the fluorocarbons exhibited the best compatibility with NF_3 . Under load conditions, several of the metals were found to be susceptible to stress corrosion cracking. Under dynamic conditions, nickel, Inconels, and the 300-series stainless steels were found to be suitable metals for use with NF_3 .

Additional tests were conducted to evaluate the compatibility of NF_3 with 15 different materials when compressed suddenly in a U-tube apparatus in which a slug of liquid was rammed into dead-ended passage with high-pressure helium push pressures up to 17.3 MPa (2515 psia) [279]. Mechanical impact tests were conducted with Teflon and Kel-F in nitrogen trifluoride/helium atmospheres and in pure nitrogen trifluoride at pressures up to 17.3 MPa (2515 psia).

At room temperature, NF_3 appears to be inert toward polymers. Even polyethylene film has been reported to show no observable deterioration after more than a month of exposure to NF_3 [259]. Samples of polyethylene, polypropylene, polystyrene, Lucite, and silicone grease were examined both visually and by differential scanning calorimetry (DSC) after 6 days of exposure to 5 atm of NF_3 at 408 K (135°C). All but Lucite and silicone grease showed a mild surface reaction. In another study, samples of Kel-F valve packing, Teflon, Viton, Neoprene, silicone rubber, Buna-N, butyl rubber, and ethylene propylene were heated for 6 weeks at 423 K (150°C) under 1.03 MPa (150 psi) of NF_3 . Similar samples were also heated under N_2 for comparison. No changes were observed in the Teflon, Viton, or Kel-F. Silicone rubber exposed to NF_3 was noticeably deteriorated; although still flexible, it was covered with cracks, was less elastic, and appeared softer. Its Shore hardness had dropped from 57 to 40. Neoprene had become considerably stiffer, harder, and brittle, and the other polymers showed extensive deterioration.

Nitrogen trifluoride is not as aggressive as elemental fluorine, yet it may cause accidental ignition if it is compressed rapidly. A strong mechanical impact shock may not always be required to initiate reactions of fluorine compounds with metals. Sudden gas-pressure increases may cause adiabatic heating and ignition. Accidental ignitions have been observed in industrial applications of nitrogen trifluoride for cleaning of semiconductor processing equipment [280].

Compatibility data of materials with NF_3 are limited and have been addressed only by companies that routinely handle NF_3 . Even more limited is the ability to conduct configuration testing of components in NF_3 to evaluate ignition-chain and reaction effects. In NF_3 systems, the cylinder valve is subjected to severe operating conditions and is known to have experienced fires in service. A new testing approach was developed to positively ignite the non-metallic seat of a cylinder valve pressurized with NF_3 [281]. The goal of the work was to investigate whether the ignition of the seat would kindle the surrounding sub-components of the valve and, ultimately, whether a kindling reaction would develop that could breach the valve body. The ignition concept of the test method consisted of electrically heating a thin section of wire positioned across the seat to act as a promoter. The concept required minimal modifications to the valve, and the overall valve design remained consistent with normal operation. The assembled valves were tested at a pressure of 10.3 MPa (1500 psig), and no burn-through was observed during any of the tests. The post-test valve disassembly and inspection confirmed that the wire fused and successfully ignited the seat, but the seat retainer and surrounding subcomponents did not burn. All of the other parts of the valve were unaffected by the ignition and consumption of the non-metallic seat. The test provided a new approach for evaluating the propagation propensity of NF_3 components containing non-metallic materials.

1.6 Toxicity of Nitrogen Trifluoride

1.6.1 Inhalation Toxicity of Nitrogen Trifluoride

Already the discoverer of NF_3 , Ruff reported in 1931 that this gas is very toxic: 1% NF_3 in air proved to be fatal to a group of mice within 40 min. Lower concentrations (0.2% NF_3) were tolerated without visible effects. A cat that was forced to inhale 1% NF_3 for 20 min died after 4 h. Nitrogen trifluoride is not a lung poison but a blood poison. The color of the blood changes in the presence of NF_3 , but the suspected formation of methemoglobin could not be confirmed. Unlike PF_3 or CO, NF_3 does not form a complex with hemoglobin. Some industry brochures recommend a MAC of 100 ppm and list a lower limit of toxic effects at 300 ppm, but they do not provide the foundation for such recommendations.

Single-exposure episodes of rats to concentrations in excess of 1000 ppm NF_3 caused methemoglobinemia [282]. Concentrations of 2500 or 1000 ppm NF_3 caused death after 4 h of exposure. Exposures to higher concentrations resulted in shorter survival times. The recovery of survivors appeared rapid, although enlarged spleens were seen in many of the surviving animals. Repeated exposures 7 h/d, 5 d/week of male and female rats to 100 ppm NF_3 for 4.5 months resulted in slight to moderate pathologic changes in the livers and kidneys of rats of both sexes. An increase in the average weight of the liver, kidneys, and spleen of the male rats was also found. Microscopic examination of liver and kidney tissues showed degenerative changes in rats of both sexes, but damage was more pronounced in female rats. No evidence of fluorosis of the teeth or deposition of fluorine in the teeth or bone was observed, although a very slight increase in total fluorine in the urine was detected. The concentration of NF_3 in work areas where repeated human exposure is likely should be limited to well below 100 ppm until more adequate information is available. Nitrogen trifluoride does not possess warning properties adequate to prevent excessive exposure; therefore, monitoring of work spaces by instruments is recommended. Analysis by IR absorption is extremely sensitive to this material and with a suitable gas cell should provide a method suitable for continuous monitoring.

Nitrogen trifluoride exposures of groups of rats were made in an $18 \times 18 \times 27$ -in aluminum chamber fitted with transparent Kel-F view ports and lined with Teflon-surfaced glass cloth [283, 284]. Groups of 10 rats were exposed to 15–1000 ppm NF_3 . The reaction of NF_3 with hemoglobin *in vitro* has been studied in a closed system in which the amount of NF_3 utilized and methemoglobin formed during each reaction was varied. The behavior of blood or suspensions of erythrocytes in dynamic atmospheres of NF_3 was studied in a small exposure chamber. Each mol of NF_3 oxidized more than 1 mol of heme. Animals exposed to 10000 ppm NF_3 showed very definite respiratory distress as well as generalized depression to the extent that they were non-responsive to external stimulation. The methemoglobin formed was superficially detectable in eye color and in the coloring of the mucous membranes and extremities. The LD50 of

NF₃ gas injected intraperitoneally was about 8.25 mL (0.37 mmol)/kg. Each animal observed at the terminal stages of NF₃ poisoning was found to be suffering from 60–70% conversion of hemoglobin to methemoglobin, which is presumably a lethal level.

Blood samples of rats exposed to high concentrations of NF₃ were analyzed for concentrations of serum glutamic oxalacetic transaminase, serum isocitric dehydrogenase, blood lactate, and methemoglobin [285]. Inhalation of 10000 ppm NF₃ for 45 min resulted in the conversion of 37% of the total rat hemoglobin to methemoglobin and a sixfold increase in blood lactate at the end of exposure. Both parameters had returned to normal 4 h later. Serum isocitric dehydrogenase did not change detectably as a result of the exposure. Serum glutamic oxalacetic transaminase was unchanged at 1 h but was increased twofold to threefold by 6 h post exposure and remained elevated for as long as 24 h after the exposure.

Rats were exposed for 1 min to tracheal inhalation of NF₃ gas to determine its toxic effects on the cardiovascular system [286]. The exposed rats had a definite decrease in diastolic pressure, systolic pressure, and heart rate. Similarly, rats that pre-breathed oxygen for 5 min before exposure had the same changes in the cardiovascular system as those breathing only NF₃. However, animals that inhaled oxygen for 5 min immediately after exposure to NF₃ showed a temporary increase in diastolic pressure, systolic pressure, and heart rate.

The distribution of fluoride in rat tissues has been studied over periods of 20–48 h following acute intoxication with NaF, NF₃, N₂F₄, ClF₃, and BrF₅ [287]. The data do not suggest the existence of any fluoride-bearing degradation products that behave differently from fluoride ion. NF₃ and N₂F₄ intoxication resulted in persistently high concentrations of fluoride in erythrocytes.

The stoichiometry of the reaction of hemoglobin with NF₃ *in vitro* and *in vivo* was measured. In examining the nature of this reaction, the ratio of mols of NF₃ utilized/equivalents of methemoglobin formed was measured in aqueous solutions of hemoglobin and in acetone solutions of crude ferroprotoporphyrin, as well as in intact anesthetized dogs [288]. Results suggested that 1 mol NF₃ mediates or participates in the oxidation of 3 heme equivalents.

Short-term exposures of rats, mice, dogs, and monkeys to acute concentrations of NF₃ were performed, and median lethal concentrations were determined for rats and mice [289]. It appeared that the immediate effects of acute exposure to NF₃ were caused by extensive methemoglobin formation and the resulting anoxia. Dogs surviving exposure to 9600 ppm for 60 min exhibited a Heinz body anemia, with red blood cell count, hemoglobin, and hematocrit decreasing 33% to minimum values by the end of the second week post exposure. Recovery of hematologic values to pre-exposure levels was attained in 40 d. In dogs, the anemia caused by a dose level of 120000 ppm-min was severe enough to invalidate that dose as an emergency exposure limit (EEL). At 30000 ppm-min, however, no detectable anemia occurred, and no other toxic effects were discernible. The results of experiments conducted at sub-acute levels jus-

tified recommending an upward revision of the EEL to 30000 ppm-min from the proposed U.S. National Academies of Science, Engineering, and Medicine National Research Council value of 3000 ppm-min.

The acute toxicity of nitrogen trifluoride has been shown to be due to massive formation of methemoglobin, with death ensuing from the resulting anoxia. Previous studies did not quantitate the acute toxicity of NF_3 by determination of LC50 values. Additional investigations were undertaken to evaluate the LC50 at 15, 30, and 60 min in rats, mice, beagle dogs, and rhesus monkeys (Table 13) [290]. The LC50 for a 50-min exposure would be 7500 ppm in mice, 6700 ppm in rats, 9600 ppm in dogs, and 10000 ppm in monkeys. There were no detectable physiologic changes in dogs or monkeys at 1000 ppm/30 min or 500 ppm/1 h. The gaseous NF_3 was introduced into the chamber air stream after passage through a sodium fluoride trap to remove any hydrogen fluoride that might have been present in the NF_3 .

Table 13: Nitrogen trifluoride lethal toxicity levels for four different types of test animals.

Time, min	Rats	Mice	Dogs	Monkeys
15	26700	19300	38800	24000
30	11700	12300	20200	14100
60	6700	7500	9600	9200

Data source: [290]

Additional experiments were conducted to determine which short-term exposure levels of NF_3 would have no significant effects on all species tested. The latter series of tests was carried out to aid in setting up realistic EELs. EEL values for NF_3 at one time proposed by the U.S. National Academies of Science, Engineering, and Medicine Committee on Toxicology were 100 ppm for 30 min and 50 ppm for 60 min, corresponding to a dose level of 3000 ppm-min. It was later recommended to raise the EEL to 30000 ppm-min, but the Committee eventually settled on an EEL of 22500 ppm-min.

As of 2014, the ACGIH TLV-TWA was 10 ppm. The National Institute for Occupational Safety and Health (NIOSH) Immediately Dangerous to Life and Health (IDLH) limit for NF_3 was originally 2000 ppm and was revised in 1995 to 1000 ppm for a 10-min exposure [291, 292].

The Committee on Toxicology has recommended the following EELs for spills of NF_3 on or around rocket launching sites or in the testing of rocket motors or lasers: 10 min, 2250 ppm; 30 min, 750 ppm; and 60 min, 375 ppm [293]. See also [294].

1.7 Environmental Effects of Nitrogen Trifluoride

1.7.1 Atmospheric Effects of Nitrogen Trifluoride

If accidentally released into the atmosphere, nitrogen trifluoride will diffuse to the upper stratosphere and absorb energy from the incoming solar radiation. Gradual hydrolysis will convert it to hydrogen fluoride, which, of course, is a very unpleasant environmental pollutant. The global-warming potential (GWP) of NF_3 on a 100-year time scale was calculated to be 16800 times that of CO_2 , although other kinetic studies suggested a slightly lower GWP due to a shorter stratospheric lifetime. Regardless of small uncertainties in its calculated lifetime, NF_3 is a stronger greenhouse gas than the compounds it replaced in some industrial applications (such as CF_4 and C_2F_6). Of the Kyoto Protocol-listed gases, its GWP is second only to that of SF_6 (which has a 100-year GWP of 22800).

Nitrogen trifluoride was included in the group of Kyoto-recognized greenhouse gases only with effect from 2013 and the start of the second commitment period of the Kyoto Protocol. It has an estimated atmospheric lifetime of 740–550 years [295]. NF_3 production has grown from 1992, when less than 100 metric tons were produced, to an estimated 4000 metric tons in 2007 and continues to increase. World production of NF_3 was expected to reach 8000 tons a year by 2010. It was predicted that the maximum atmospheric NF_3 concentration is less than 0.16 parts per trillion (ppt) by volume, which would provide less than 0.001 Wm^{-2} of IR forcing [169].

The mean global tropospheric concentration of NF_3 has risen quasi-exponentially from about 0.02 ppt at the beginning of the record in 1978 to a 2008 value of 0.454 ppt, with a rate of increase of 0.053 ppt/year, or about 11% per year, and with an interhemispheric gradient that is consistent with these emissions occurring overwhelmingly in the northern hemisphere [296]. This rate of increase corresponds to about 620 metric tons of current NF_3 emissions globally per year, or about 16% of the global NF_3 production estimate of 4000 metric tons/year.

The amount of NF_3 emitted from the electronics industry around the world in 2006 was estimated to be between 3.6 and 56 metric tons [297]. Although the cumulative amount of NF_3 in the atmosphere currently would be negligible based on the predicted ratio (the order of 10^{-6} to 10^{-7}) of equivalent CO_2 emission from NF_3 to total equivalent CO_2 emissions from other industries and consumers, it was deemed to be necessary to adopt the available abatement and also to monitor the concentration of NF_3 in workplaces in order to reduce the overall environmental and health impacts of various semiconductor processes [298].

It was estimated that the global emissions of NF_3 in 2011 were $1.18 \pm 0.21 \text{ Gg/year}$, or $\sim 20 \text{ Tg CO}_2\text{-eq/year}$ (CO_2 -equivalent emissions based on a 100-year GWP of 16600 for NF_3). The 2011 global mean tropospheric dry-air mol-fraction of NF_3 was $0.86 \pm 0.04 \text{ ppt}$, resulting from an average emissions growth rate of $0.09 \text{ Gg} \cdot \text{year}^{-2}$ over the prior decade. In terms of CO_2 equivalents, current NF_3 emissions represent between 17 and 36% of the emissions of other long-lived fluorinated compounds from electronics

manufacturing. There is a continuing need for improvements in NF_3 emissions-reduction strategies to keep pace with its increasing use and to slow its rising contribution to anthropogenic climate forcing.

It has been argued that the contribution of NF_3 emissions to overall global warming is overestimated and that the contribution of nitrogen trifluoride to the CO_2 budget of thin-film solar cell production is compensated by the fossil fuel-burning savings potential of the photovoltaic technology. Amorphous-silicon and nanocrystalline-silicon thin-film photovoltaic modules are made in high-throughput manufacturing lines that necessitate quick cleaning of the reactor. Using and emitting NF_3 as the cleaning agent has triggered concerns by environmentalists, but industry quantified the life-cycle emissions of NF_3 in photovoltaic manufacturing on the basis of actual measurements at the facilities of a major producer of NF_3 and of a manufacturer of photovoltaic end-use equipment [299]. But, of course, that leaves all the NF_3 emitted during the production of flat-screen TVs, which has no environmental benefit.

1.7.2 Biospheric Effects of Nitrogen Trifluoride

The effects of NF_3 or N_2F_4 on seeds and seedlings of bean, corn, pea, squash, and Sudan grass were measured by exposing dry seeds to a gaseous 100% NF_3 atmosphere for 1 to 8 h, which caused inhibition of subsequent germination [300]. Exposure of seeds to a 10% N_2F_4 atmosphere for 1 h completely inhibited germination of all five species of seeds. Concentrations of N_2F_4 or NF_3 up to 10000 ppm in air were required to cause visible damage of plant seedlings after a 30 to 60-min exposure period. The exposed seeds and seedlings were analyzed for fluoride content.

1.8 Applications of Nitrogen Trifluoride

1.8.1 Semiconductor Industry

Significant use of NF_3 began with the replacement of perfluorocarbons in the 1990s in the semiconductor industry for chemical etching because of better process performance and a supposed reduction in carbon dioxide-equivalent greenhouse-gas emissions and ozone-depletion potential. It is used for cleaning of CVD reactors and, more recently, in the manufacturing of liquid crystal flat-panel displays and thin-film photovoltaic cells. Prior to that, gases that were in use for the various processing steps associated with semiconductor device fabrication included CF_4 , CF_4/O_2 , and SF_6 . But then it was found that NF_3 worked better than any of those chemicals, and so its use increased for a while [301], but only until NF_3 was also identified as environmentally damaging because of its high GWP. It could then no longer be vented above-roof to the atmosphere. CVD chamber cleaning is now done with elemental difluorine gas generated on site by electrolysis of molten KHF_2 .

1.8.2 Lasers

There are two types of lasers in which NF_3 might be used: electric discharge-pumped KrF lasers and chemical fluorine-hydrogen or fluorine-deuterium lasers. Because these lasers involve reactions between an NF_3 oxidizer and hydrogen-containing fuels, these reactions should be discussed under rocket propellant combustion headings in a future volume on bipropellant combinations, but we preferred to summarize the laser applications here since they are not truly a rocket propulsion application.

In a pulsed $\text{NF}_3 + \text{H}_2$ hydrogen fluoride laser, the reaction is initiated by a short-duration electric discharge. The pulsed laser was chosen in an attempt to obtain short-duration, high-intensity pulses for laser fusion. In the $\text{NF}_3 + \text{H}_2$ laser, the electric discharge dissociates a fraction of the NF_3 to give F atoms and other species that do not participate in laser action. The chemical reaction

creates vibrationally and rotationally excited HF^* , which lases. It is also possible to build a pulsed CW laser using a mixture of F_2 and H_2 so that the chemical reaction

produces additional excited HF^* , and it also creates a new $\text{F}^{\cdot}$ atom to replace the one consumed in the first reaction, sustaining a chain reaction [302]. Typically, in a combustion-driven chemical laser, an excess of atomic fluorine is produced in the combustor by burning a fuel, and the combustor products, including the atomic fluorine, are expanded at supersonic speed into a cavity with parallel mirrors. Hydrogen or deuterium fuel is introduced into the cavity and reacts with the atomic fluorine to form the lasing species HF^* or DF^* . Decay of the lasing species to ground level produces laser emission at 2.6–2.9 μm for HF and 3.6–4.0 μm for DF. Cavity pressures vary from about 0.13 to 2.67 kPa (1–20 mm Hg) and cavity temperatures from about 300 to 900 K. The spent reactants must be removed from the cavity at supersonic speeds since the ground-state species will quench the lasing reaction.

A mixture of NF_3 and Ar was passed through an RF discharge in a flow system to produce, among other species, $\cdot\text{F}$ and $\cdot\text{NF}_2$ [303]. When H_2 , D_2 , or CH_4 was added downstream, reactions with $\cdot\text{F}$ atoms produced vibrationally excited HF or DF together with $\cdot\text{H}$, $\cdot\text{D}$, or $\cdot\text{CH}_3$. The latter free radicals can react with NF_2 to produce electronically excited NF:

A vibrational-to-electronic energy-transfer process between the products of this reaction then produced the next higher state of NF:

A similar transfer process has also been found between the electronically excited $a^1\Delta$ states of O_2 and NF:

The $H^\bullet$ or $D^\bullet$ atoms, but not the $\bullet CH_3$ radicals, were found to react with either $NF(a^1\Delta)$ or $NF(X^3\Sigma^-)$ to produce electronically excited $N(^2D)$ atoms, which in turn reacted with the $NF(a^1\Delta)$ molecules to produce $N_2(B^3\Pi_g)$. Some emission was observed at 3344 Å, which was attributed to $NF(A^3\Pi)$ that had not been previously reported.

A peak density of the electronically excited free-radical species $NF(a^1\Delta)$ of $2.4 \times 10^{-9} \text{ mol cm}^{-3}$ has been chemically produced in a subsonic laser device operating on hydrogen and nitrogen trifluoride [304]. This high concentration confirmed previous analyses and predictions of the chemical system. This was a concentration scale-up by a factor of 10^4 from previous flow-tube results.

The reaction (1) of $H(^2S)$ atoms with $\bullet NF_2$ radicals forms metastable excited $NF(a^1\Delta)$ molecules with a branching ratio greater than 0.9 [305]:

Subsequent reactions also form the $b^1\Sigma^+$ state of NF. The strong 0,0 bands of the a,X and b,X transitions of NF are near 874 and 528 nm, and their emission intensities were used to follow the excited-state concentrations.

The reaction of hydrogen atoms with $\bullet NF_2$ was studied in a flow tube using pulsed KrF laser initiation of $H_2/NF_2/Ar$ mixtures at 440 K [306]. The quantum yield for $NF(a)$ production from the 249-nm photolysis of NF_2 was 0.10 ± 0.05 . Several important reactions in this system were investigated, and rate coefficients were determined at 440 K. A value of $(1.03 \pm 0.20) \times 10^{-30} \text{ cm}^6/\text{molecule}^2$ was obtained for the three-body recombination of F atoms with $\bullet NF_2$ and Ar. Rate constants for the relaxation of $HF(v=2)$ and $HF(v=3)$ by $\bullet NF_2$ are $(9.7 \pm 1.0) \times 10^{-14}$ and $(2.5 \pm 0.5) \times 10^{-13} \text{ cm}^3/\text{molecule}$, respectively. Study of the quenching of $NF(a)$ by $\bullet NF_2$ yielded a rate coefficient of $(2.7 \pm 1.0) \times 10^{-16} \text{ cm}^3/\text{molecule}$. That indicates that the disproportionation of $NF(a)$ is three orders of magnitude slower than that of ground-state NF. Modeling results were presented that agreed well with experimental data.

The reaction of $\bullet H$ atoms with $\bullet NF_2$ radicals produces metastable $NF(a^1\Delta)$ radicals and vibrationally excited HF as primary products [307]:

Reactions in a photolytically excited HF chemical laser based on a NF_3/H_2 gas mixture were modeled using known kinetic rates [308].

A flowing afterglow method was used to study a number of reactions of importance in KrF lasers using NF_3 as the fluorine donor, and total rate constants for $Kr^*(^3P_2) + NF_3$ and $Kr^+ + NF_3$ were reported [309]. The thermal energy attachment

coefficient has been measured for NF_3 , and the cross-section for the electron excitation process $\text{Kr}^*(^3\text{P}_2) + \text{e} \rightarrow \text{Kr}^*(^3\text{P}_1) + \text{e}$ has been estimated.

Based on an urgent requirement for NF_3 , in October 2002 the U.S. Defense Energy Support Center/Defense Logistics Agency awarded an emergency contract to Advanced Specialty Gas in Dayton, Nevada, for 1000 lb of NF_3 [310]. Delivery to White Sands Missile Range in New Mexico was required no later than November 2002. Arrangements were made to fill a government-provided trailer coming from Amarillo, Texas, to the contractor's plant in Nevada, and then to transport it to White Sands Missile Range, and all arrangements were accelerated to ensure delivery by the required delivery date. White Sands Missile Range received the 1000 lb of NF_3 on 3 November 2002. Another solicitation for procurement of another 1000 lb of NF_3 was issued in 2003. It is not known whether this effort still continues. NF_3 is still listed in the propellant inventory.

1.8.3 Photography Flash Bulbs

The reaction of NF_3 with metals (zirconium or aluminum) creates a very hot flame with a bright light, similar to daylight in color and suitable for flash bulbs for photography (prior to the invention of the electronic strobe light) [311–313]. The use of such chemical flash bulbs was abandoned after more efficient electric strobe tubes became available, which are now found on every digital camera.

2 Tetrafluoroammonium Salts

Although initial thermodynamic and molecular orbital calculations let the stability of NF_4^+ salts appear unlikely [200, 201], skilled experimenters did succeed in synthesizing several NF_4^+ salts that might even be useful as oxidizers in solid rocket propellants or fluorine gas generators.

The chemistry of tetrafluoroammonium salts was pioneered by Christie and colleagues at Rocketdyne, at that time a division of Rockwell International in Canoga Park, California. The list of NF_4^+ publications and patents from that group fills several pages, and only the most remarkable topics are discussed here to the extent that they relate to their potential use as oxidizers in rocket propellants or as gas generants for fluorine generators in chemical lasers.

Close to 100 tetrafluoroammonium salts have been synthesized since NF_4^+ was first discovered, and there are some good summary reviews of the work that has been performed, including [314–316].

The lone electron pair in ammonia as well as nitrogen trifluoride makes both of these molecules a Lewis base, where they can share that electron pair with Lewis acids. The resulting adducts can have saline character. Nitrogen trifluoride and other

compounds carrying the difluoroamino group can form Lewis adducts with a variety of Lewis acids, such as BF_3 , BCl_3 , PF_5 , and SO_2 , which are stable at low temperatures [317]. The relative base strengths of difluoroamines decreased in the order

IR spectra have shown that where complex formations occur, the intermolecular binding was through donation of the nitrogen lone-pair electrons to the Lewis acid.

2.1 Preparation of Tetrafluoroammonium Salts

The first tetrafluoroammonium, or tetrafluoronitronium(V) as it was once called, salt was $[\text{NF}_4]^+[\text{AsF}_6]^-$, prepared by Christe, Guertin, and Pavlath in 1966 [318, 319]. When NF_3 , AsF_5 , and F_2 in a 1:1:1 mol ratio were subjected to a low-temperature glow discharge, a white crystalline powder formed that was stable and non-volatile at 298 K. In differential thermal analysis (DTA) it decomposed at about 540 K. The compound was very hygroscopic and easily hydrolyzed to an initially blue solution with the evolution of gas. XRD showed the cation to have a tetragonal structure with unit cell dimensions of $a = 7.70 \text{ \AA}$ and $c = 5.73 \text{ \AA}$, with two molecules per unit cell [320].

The reaction of nitrogen trifluoride, difluorine, and Lewis acids such as AsF_5 or SbF_5 in an autoclave at high pressures (50–200 atm) and high temperatures between 373 and 473 K (100 and 200 °C) leads to the corresponding tetrafluoroammonium salts [321–323].

Complex fluoro cations are generally prepared through fluorine abstraction from the parent molecule by means of a strong Lewis acid. This was first demonstrated in 1949 for BrF_3 . In the case of NF_4^+ salts, this approach was impossible because the parent molecule NF_5 is unknown and is unlikely to exist owing to the validity of the octet rule for first-row elements such as nitrogen and fluorine. The synthesis of NF_4^+ from NF_3 and F^+ is preempted by the fact that fluorine is the most electronegative element; hence, F^+ should be extremely difficult, if not impossible, to prepare by chemical means.

Many reactions previously requiring the use of the prohibitively expensive PtF_6 may now be carried out at reasonable expense by the use of Lewis acid–promoted activated fluorine. Two direct methods for the synthesis of $[\text{NF}_4]^+$ salts are now available, based on the reaction of NF_3 with either $[\text{KrF}]^+$ salts

or the reaction of NF_3 with F_2 and a strong Lewis acid in the presence of an activation energy source

Four different activation energy sources have been used for the direct syntheses of $[\text{NF}_4]^+$ salts: heat, UV light, glow discharge, and X-ray bremsstrahlung. Of these, the thermal synthesis is most convenient and provides the starting material required for the syntheses of other $[\text{NF}_4]^+$ salts by indirect methods. For the syntheses of pure $[\text{NF}_4]^+$ salts on a small scale, low-temperature UV photolysis is preferred.

When gaseous mixtures of NF_3 , F_2 , and the strong Lewis acids SbF_5 , AsF_5 , or BF_3 were exposed to unfiltered UV irradiation, the corresponding $[\text{NF}_4]^+$ salts were formed rapidly and reproducibly. Using AsF_5 or BF_3 and sapphire reactor, the following reactions occurred:

However, the yield of the NF_4 salt was less than 1%. This low yield appeared not to be caused so much by a slow reaction rate but by deposition of the solid product on the reactor walls, thereby preventing further irradiation of the reactants. In the case of SbF_5 and a quartz reactor, all of the SbF_5 starting material was consumed in less than 3 d [324].

Exposure of $\text{NF}_4^+ \text{AsF}_6^-$ and $\text{NF}_4^+ \text{SbF}_6^- \cdot 0.8 \text{SbF}_5$ to ^{60}Co γ rays at 77 K gave two paramagnetic centers, one of which was shown by electron spin resonance (ESR) spectroscopy to contain one nitrogen atom and three equivalent fluorine atoms. Based on its magnetic properties, it was identified as pyramidal $\cdot\text{NF}_3^+$, a radical cation [325].

One of the intermediates in the synthesis of NF_4^+ salts may be $\cdot\text{NF}_3^+$. UV photolysis of both the $\text{NF}_3\text{-F}_2\text{-AsF}_5$ and the $\text{NF}_3\text{-F}_2\text{-BF}_3$ systems produced an intensely violet species that exhibited the ESR signal typical for $\cdot\text{NF}_3^+$ cation free radical [326]. The observation of identical signals for both the BF_3 -containing and the AsF_5 -containing systems proved that the signal must be due to a species not containing boron or arsenic.

Many tetrafluoroammonium salts have been prepared by metathetical reactions where the equilibrium between four different salts can be shifted in the desired reaction only if one of the products is insoluble and precipitates, such as AgCl or AgI . A better method is to load the $[\text{NF}_4]^+$ cation onto a cation exchange resin or load the anion onto graphite acting as an anion exchange medium [327]. See also [328].

2.2 Molecular Structure of Tetrafluoroammonium Salts

Although NF_4 salts had been known for 20 years, the exact structure of the NF_4^+ cation was not known for several years. From ^{19}F NMR spectra it was known that in solution NF_4^+ is an ideal tetrahedron. Vibrational spectra of many NF_4^+ salts indicated that in the solid state, the NF_4^+ cations are also essentially tetrahedral. From the general va-

lence force field, the bond length in NF_4^+ was been estimated to be $\sim 1.31 \text{ \AA}$. This value was supported by *ab initio* calculations, which resulted in a value of $1.32 \text{ \AA}$. ^{19}F NMR, IR, and Raman spectra confirmed the ionic structure of NF_4^+ in the solid state and in HF solution. The $[\text{NF}_4]^+$ cation has four equivalent fluorine atoms in a tetrahedral configuration (space group T_d) [329, 330].

The ESR spectra of the $^{14}\text{N}^+\text{F}_3$ and $^{15}\text{N}^+\text{F}_3$ radical cations were observed over the temperature range 15–340 K [331]. The radical cations were generated either by γ -irradiation of NF_4^+ salts or by low-temperature UV photolysis of NF_3/F_2 /Lewis acid mixtures. An analysis of the observed spectra was supported by computer simulations and the observed ^{15}N isotopic data. The spin-density distributions indicated that $\text{NF}_3^{+\bullet}$ is pyramidal but that within the isoelectronic series BF_3^- , $^+\text{CF}_3$, and NF_3^+ , the planarity of the radicals increases from BF_3^- toward NF_3^+ .

The molecular structure of fluoronitrogen cations and π - and σ -fluoro effects were studied by ^{14}N and ^{15}N NMR spectroscopy of N–F cations in comparison to N–H cations [332]. These shifts in the NMR spectra were described as σ fluoro effects and were explained, at least in part, by the decrease in electron density on nitrogen.

The estimate of the bond length in NF_4^+ from the published general-valence force field was revised, and a value of $1.31 \text{ \AA}$ was suggested [333].

The room-temperature tetragonal structure of $\text{NF}_4^+\text{BF}_4^-$ has been determined by a combination of single-crystal XRD and vibrational spectroscopy [334]. This compound crystallizes in the tetragonal space group $P4_21m$, with $Z=4$ and unit cell dimensions of $a = 9.92(1) \text{ \AA}$ and $c = 5.23(1) \text{ \AA}$. The structure is made up from an approximately tetrahedral NF_4^+ cation with a bond length of $1.30 \text{ \AA}$ and a BF_4^- anion that rotates or oscillates around a threefold axis along one of its bonds.

2.3 Thermodynamic Properties of Tetrafluoroammonium Salts

Even before the first tetrafluoroammonium salts were synthesized and characterized, speculation about their potential stability had already started [200, 201]. Calculations were made of the predicted enthalpies of formation and decomposition of tetrafluoroammonium salts. A highly desirable rocket propellant oxidizer would be tetrafluoroammonium perchlorate, which has yet to be made and stabilized. The lattice energy of that salt would be 486 kJ/mol (116 kcal/mol), and the heat of formation was predicted to be somewhere between $+88$ and $+234 \text{ kJ/mol}$ ($+21$ and $+56 \text{ kcal/mol}$).

The decomposition, solid-phase change, and formation enthalpies for NF_4BF_4 , NF_4PF_6 , NF_4AsF_6 , NF_4SbF_6 , NF_4GeF_5 , and $(\text{NF}_4)_2\text{GeF}_6$ were determined by differential scanning calorimetry (DSC) [335]. The enthalpies of reaction with water of NF_4BF_4 , NF_4PF_6 , NF_4AsF_6 , and NF_4SbF_6 were measured and used to obtain an alternate set of formation enthalpies for these NF_4 compounds. Recommended values for ΔH_f° in the solid state are as follows: $\text{NF}_4\text{BF}_4 - 1410 \pm 10 \text{ kJ/mol}$, $\text{NF}_4\text{SbF}_6 - 1669 \pm 12 \text{ kJ/mol}$, $\text{NF}_4\text{AsF}_6 - 1538 \pm 1 \text{ kJ/mol}$, $\text{NF}_4\text{PF}_6 - 1841 \pm 7 \text{ kJ/mol}$, $\text{NF}_4\text{GeF}_5 - 1473 \pm 1 \text{ kJ/mol}$, and

$(\text{NF}_4)_2\text{GeF}_6 - 1606 \pm 5 \text{ kJ/mol}$. The thermally most stable salt in this group was NF_4SbF_6 , with an onset of exotherm at 578 K (305 °C). The thermally least stable salt was NF_4GeF_5 , with beginning decomposition at 374 K (101 °C).

DSC study of the thermal decomposition of $(\text{NF}_4)_2\text{NiF}_6$ and NF_4SbF_6 gave standard enthalpies of formation of -1033 and -1649 kJ/mol , respectively [336].

2.4 Applications of Tetrafluoroammonium Salts

Tetrafluoroammonium salts were initially only of academic interest, and it was not until 1971 when, with the advent of chemical HF-DF lasers, the interest in storable NF_3 -F sources was renewed [337]. It became rapidly obvious that NF_4 salts were the most promising oxidizers for solid-propellant NF_3 -F₂ gas generators for combustion-driven chemical lasers. The concept of such a gas generator was conceived by Pilipovich at Rocketdyne [338]. These propellants consist of a highly over-oxidized grain using NF_4^+ salts as the oxidizer. Burning these propellants with a small amount of fuel, such as aluminum powder, generates sufficient heat to thermally dissociate the bulk of the oxidizer and generate fluorine atoms. This technology was further developed for several years at Rocketdyne [339]. It offers significant logistics and safety advantages over cryogenic or storable liquid fluorine oxidizers. In a chemical HF-DF laser, F atoms are generated by burning F₂ in a pre-combustor with a fuel, such as hydrogen:

The F atoms are subsequently reacted with a cavity fuel, such as D₂, to produce vibrationally excited DF* as the active lasing species:

In the original solid F atom generator concept, the F atoms were directly generated by burning the solid propellant grain, thus eliminating the need for a pre-combustor. This concept was demonstrated for NF_4BF_4 with a small percentage of Teflon serving both as a fuel and a binder. The heat of reaction $(\Delta H)_{\text{react}}$ is sufficient to dissociate most of the NF_3 and F₂ to F atoms and N₂:

From a practical point of view, however, such a direct generation of F atoms was not desirable, since it did not allow the necessary flow controls and flexibility required for on-off operation. Consequently, the concept was modified to that of an NF_3 -F₂ molecule generator, using a gas catch tank for interim storage. Further modification of this concept became necessary when system analysis data revealed that gaseous by-products of high molecular weight and low C_p/C_v significantly degraded the per-

formance of a laser. Consequently, an $\text{NF}_3\text{-F}_2$ gas generator was desired that would produce no gases other than NF_3 and F_2 . The latter objective can be achieved by a so-called clinker system in which the BF_3 by-product is converted by an alkali metal fluoride to a non-volatile BF_4 salt:

Whereas the feasibility of such a clinker system approach has been well demonstrated, the addition of KF lowered the $\text{NF}_3\text{-F}_2$ yield per mass of solid propellant, and the possibility always exists of having incomplete clinkering. Realizing these limitations, Rocketdyne developed “self-clinkering” NF_4 salts. Such self-clinkering formulations contain $(\text{NF}_4)_2\text{SnF}_6$, NF_4SnF_5 , $(\text{NF}_4)_2\text{TiF}_6$, $\text{NF}_4\text{Ti}_2\text{F}_9$, $\text{NF}_4\text{Ti}_3\text{F}_{13}$, or $\text{NF}_4\text{Ti}_6\text{F}_{25}$ [340–342]. These are salts derived from anions that will yield NF_4^+ salts which are the key ingredients for solid-propellant $\text{NF}_3\text{-F}_2$ gas generators. The reaction leaves behind non-volatile fluorides, such as SnF_4 or TiF_4 after thermal decomposition. Test firings of these salts in formulations, however, revealed problems. The “non-volatile” fluorides were found to be not so non-volatile after all, and they either sublimed or were blown as fine dust throughout the system. Furthermore, very high fuel levels were required to burn these formulations. To be able to fire these formulations, it was necessary to add some alkali metal fluorides as burning aids and to develop burning-rate modifiers. It was possible to increase the fluorine yields by using the lighter LiF instead of KF in some of these formulations and to use less than the stoichiometric amount. The NF_4^+ salt with the highest theoretical fluorine yield (64.6 mass-% before burning) was $(\text{NF}_4)_2\text{NiF}_6$ (Table 14).

However, this salt had the disadvantage of being of limited thermal stability and did not completely meet long-term storability requirements. An alternate salt with high fluorine yield was $(\text{NF}_4)_2\text{MnF}_6$, a compound that approached the fluorine yield of the nickel salt but was thermally more stable [343].

The thermal decompositions of NF_4BF_4 and NF_4AsF_6 were studied in a sapphire reactor at different temperatures by total-pressure measurements, at 455, 462, and 464 K (182, 189, and 191 °C) for NF_4BF_4 and 473, 491, 500, and 511 K (200, 218, 227, and 238 °C) for NF_4AsF_6 [344]. It was found that the rates are those of a 3/2 order reaction. From the temperature dependence of the decomposition rates, the global activation energies of NF_4BF_4 and NF_4AsF_6 decomposition were calculated as $E_{\text{act}} = 153 \pm 3.3 \text{ kJ/mol} = 36.6 \pm 0.8 \text{ kcal/mol}$ and $187 \pm 17.6 \text{ kJ/mol} = 44.7 \pm 4.2 \text{ kcal/mol}$, respectively. The following reversible reaction mechanism was proposed:

Table 14: Theoretical fluorine yields of NF₃-F₂ gas generator compositions.

System	Usable F content (mass-%) before burning	Comments
(NF ₄) ₂ XeF ₈	71.7	Requires no clinkering agent; difficult to synthesize; hydrolyzes to shock-sensitive XeO ₃ ; expensive
(NF ₄) ₂ BeF ₄	71.7	Unknown
(NF ₄) ₃ AlF ₆	69.3	Unknown
(NF ₄) ₂ NiF ₆	64.6	Marginal long-term storability
NF ₄ XeF ₇	62.9	Same as for (NF ₄) ₂ XeF ₈
(NF ₄) ₂ MnF ₆	59.9	Requires burning aid
(NF ₄) ₂ SiF ₆	59.0	Requires clinkering agent
(NF ₄) ₂ TiF ₆	55.6	Requires burning aid
NF ₄ BF ₄	54.0	Requires KF as clinkering agent
(NF ₄) ₂ GeF ₆	51.8	Requires clinkering agent
NF ₄ AlF ₄	49.2	Requires burning aid
NF ₄ Be ₂ F ₅	46.8	Very toxic; requires burning aid
(NF ₄) ₂ SnF ₆	46.0	Requires burning aid
NF ₄ PF ₆	40.4	Requires clinkering agent
NF ₄ GeF ₅	36.9	Requires clinkering agent
NF ₄ AsF ₆	34.1	Requires clinkering agent; toxic
NF ₄ SnF ₅	31.3	Requires burning aid
NF ₄ SbF ₆	29.2	Requires clinkering agent
NF ₄ BiF ₆	23.0	Requires clinkering agent

Data source: [337]

The tendency to form NF₄ salts by thermal activation strongly decreases with decreasing Lewis acid strength in the order SbF₅ > AsF₅ > PF₅ > BF₃. Consequently the thermal stability of the formed salts decreases in the same order. The heat of formation of NF₄BF₄ was known from previous experiments, and the heat of formation of NF₄⁺AsF₆⁻ was predicted to be about 372 kcal/mol.

The NF₄⁺ content of complex tetrafluoroammonium salts can be determined by hydrolysis of very small (500–1000 mg) samples using gasometric and gas chromatographic methods [345, 346]. The hydrolysis of tetrafluoroammonium salts according to

can sometimes proceed explosively and has to be carried out gradually at low temperatures, with intermittent cooling in liquid nitrogen or in an inert diluent. The O₂ + NF₃ gas mixture evolved can then be analyzed by GC or by fractional condensation. Examples were given for NF₄BF₄, NF₄SbF₆, NF₄BiF₆, and NF₄SnF₅, with NF₃ contents ranging from 17 to 40%.

2.5 Tetrafluoroammonium Salts with Different Anions

2.5.1 Tetrafluoroammonium Salts with Fluorine-Containing Anions

The discovery of tetrafluoroammonium salts opened up a new branch of fluorine chemistry with potential applications for rocket propellants [318, 347] and fluorinating agents. The tetrafluoroammonium cation NF_4^+ is one of the strongest fluorinating agents known.

Sometimes it is desirable to exchange the easy-to-prepare tetrafluoroborate anion with other ions with better oxidizing power or stabilizing effectiveness. Metathetical reactions work only if one of the products is either insoluble or volatile. Ion exchange can also be achieved with ion-exchange media. Traditional ion exchange resins with organic polymers would not be stable in NF_4^+ solutions in H_2F_2 . Instead, graphite can be used as an ion-exchange medium. An improved process for the production of advanced NF_4^+ salts used graphite salts as an HF-resistant and oxidizer-resistant anion-exchange medium [348].

One of the more easily prepared tetrafluoroammonium salts with all volatile constituents is tetrafluoroammonium fluorosulfonate $\text{NF}_4^+\text{SO}_3\text{F}^-$ [349]. This salt can be prepared by metathetical reaction between NF_4SbF_6 and CsSO_3F in anhydrous HF solution at 195 K (−78 °C). In HF solution, it is stable at room temperature. Removal of the solvent produces a white solid that is stable at 273 K (0 °C) but slowly decomposes at 283 K (+10 °C) to produce FOSO_2F and NF_3 in high yield.

2.5.2 Tetrafluoroammonium Salts with Complex Group 4 Transition Metal Anions

Group 4 metals include Ti, Zr, and Hf. Tetrafluoroammonium hexafluorotitanate $(\text{NF}_4)_2\text{TiF}_6$ is a potential ingredient for fluorine gas generators in chemical lasers.

Bis-perfluoroammonium hexafluorotitanate $(\text{NF}_4)_2\text{TiF}_6$ can be prepared by a metathetical reaction between Cs_2TiF_6 and NF_4SbF_6 in HF solution [350]. $(\text{NF}_4)_2\text{TiF}_6$ is a white crystalline solid and is stable to about 473 K (200 °C). It was characterized by elemental analysis and IR, Raman, ^{19}F NMR spectroscopy, and XRD. $(\text{NF}_4)_2\text{TiF}_6$ crystals have a tetragonal structure with $a = 10.715 \text{ \AA}$, $c = 11.114 \text{ \AA}$. Heating of NF_3 , F_2 , and TiF_4 to 463 K (190 °C) for 50 d at an autogenous pressure of 163 atm produced a polymeric salt of the approximate composition $\text{NF}_4\text{Ti}_6\text{F}_{25}$. $(\text{NF}_4)_2\text{TiF}_6$ has the highest usable fluorine content of any presently known NF_4^+ salt.

Improved NF_4^+ compositions for solid-propellant NF_3 - F_2 gas generators have been patented that produce NF_3 and F_2 free of volatile Lewis acids and do not require clinker-forming additives for their complexing. These self-clinkering compositions contain $(\text{NF}_4)_2\text{SnF}_6$, NF_4SnF_5 , $(\text{NF}_4)_2\text{TiF}_6$, $\text{NF}_4\text{Ti}_2\text{F}_9$, $\text{NF}_4\text{Ti}_3\text{F}_{13}$, and $\text{NF}_4\text{Ti}_6\text{F}_{25}$ [340].

The use of self-clinkering formulations based on $(\text{NF}_4)_2\text{TiF}_6$ has previously been proposed as a means of increasing the theoretically obtainable NF_3 - F_2 yield relative to that of the state-of-the-art $\text{NF}_4\text{BF}_4 \cdot 1.2\text{KF}$ formulations. However, test firings of $(\text{NF}_4)_2\text{TiF}_6$ -based formulations showed that the relatively high volatility of TiF_4

(boiling point 284 °C) resulted in the deposition of TiF_4 throughout the whole gas generator system. Such self-clinkering formulations contain $(\text{NF}_4)_2\text{SnF}_6$, NF_4SnF_5 , $(\text{NF}_4)_2\text{TiF}_6$, $\text{NF}_4\text{Ti}_2\text{F}_9$, $\text{NF}_4\text{Ti}_3\text{F}_{13}$, or $\text{NF}_4\text{Ti}_6\text{F}_{25}$ [340].

The problem of obtaining a Lewis acid-free NF_3 - F_2 gas stream from NF_4^+ compositions without clinker-forming additives is overcome by using NF_4^+ salts derived from the polymeric non-volatile Lewis acids SnF_4 (subliming at 704 °C) or TiF_4 (1 atm vapor pressure at 284 °C). The lack of acidity of SnF_4 at temperatures at which NF_4^+ salts can be formed and exist was demonstrated by heating mixtures of NF_3 , F_2 , and SnF_4 to temperatures up to 573 K (300 °C) at autogenous pressures of about 15.2 MPa (150 atm); no evidence was shown of NF_4^+ formation.

Improved compositions were patented for solid-propellant NF_3 - F_2 gas generators using $(\text{NF}_4)_2\text{TiF}_6$ and clinkering agents derived from LiF , KF , and NaF , either alone or in mixtures [351]. A sample composition of 81.44 mass-% $(\text{NF}_4)_2\text{TiF}_6$, 14.71 mass-% LiF , and 3.83 mass-% Al was fired in a typical gas generator; the residue was a clinker, and no dust had deposited in the cold trap.

2.5.3 Tetrafluoroammonium Salts with Complex Group 5 or 6 Transition Metal Anions

Group 5 metals include V, Nb, and Ta. Group 6 metals include Cr, Mo, and W. Tetrafluoroammonium pentafluorooxotungstate(VI) can be prepared by

Tetrafluoroammonium pentafluorooxotungstate(VI) is a white crystalline solid that is stable at 328 K (55 °C) but slowly decomposes at 358 K (85 °C) to yield NF_3 , OF_2 , WF_6 , and $[\text{NF}_4][\text{W}_2\text{O}_2\text{F}_9]$ [352].

2.5.4 Tetrafluoroammonium Salts with Complex Group 7 Transition Metal Anions

Group 7 metals include Mn and Re. Bis(tetrafluoroammonium) hexafluoromanganate(IV), $(\text{NF}_4)_2\text{MnF}_6$, is a compound that approached the fluorine yield of the nickel salt but was thermally more stable [343, 353]. The $(\text{NF}_4)_2\text{MnF}_6$ salt is a yellow crystalline solid that is highly soluble in anhydrous HF. At 297 K (24 °C), its solubility exceeded 1.30 g per gram of HF. It is stable at room temperature and up to 65 °C, and in the absence of fuels, it is not shock sensitive. With water, a violent reaction occurs. By analogy with the other known NF_4^+ salts, the hydrolysis was found to result in quantitative NF_3 evolution and, therefore, is a useful analytical method. At 338 K (65 °C), $(\text{NF}_4)_2\text{MnF}_6$ appears to be stable, but at about 373 K (100 °C) it starts to slowly decompose. The calculated XRD density was 2.64 g/cm³. NMR and IR spectra provided information about the molecular structure.

2.5.5 Tetrafluoroammonium Salts with Complex Groups 8, 9, 10 Transition Metal Anions

Groups 8, 9, and 10 include the iron, nickel, and cobalt transition metals. Tetrafluoroammonium hexafluoronickel(II)ate, $(\text{NF}_4)_2\text{NiF}_6$ is a powerful oxidizer, potentially useful for solid-propellant formulations and NF_3 - F_2 gas generators. $(\text{NF}_4)_2\text{NiF}_6$ can be prepared by combining Cs_2NiF_6 and $(\text{NF}_4)_2\text{SbF}_6$ in a mol ratio of 1:2.0–2.30 in anhydrous HF and removing the CsSbF_6 precipitate by filtration at -78°C [354].

DSC study of the thermal decomposition of $(\text{NF}_4)_2\text{NiF}_6$ and NF_4SbF_6 gave enthalpies of decomposition for $(\text{NF}_4)_2\text{NiF}_6$ and NF_4SbF_6 of 134.7 ± 13.0 and 245.6 ± 28.9 kJ/mol, respectively [336]. The corresponding standard enthalpies of formation were found to be -1033 and -1649 kJ/mol, respectively.

$(\text{NF}_4)_2\text{NiF}_6$ was prepared from Cs_2NiF_6 and NF_4SbF_5 by metathesis in HF as a solvent and was characterized by elemental analysis, vibrational spectroscopy, and its XRD pattern [355]. The reaction of $(\text{NF}_4)_2\text{NiF}_6$ with water is very violent and can result in explosions. The decomposition rates of $(\text{NF}_4)_2\text{NiF}_6$ were determined over the temperature range 353–401 K (80 – 128°C). The evolved gas was shown by IR and MS to be a mixture of NF_3 and F_2 in a mol ratio of about 2:3. On thermal decomposition, 1 cm^3 of solid $(\text{NF}_4)_2\text{NiF}_6$ is capable of producing 12% more useful fluorine values, i.e., in the form of F_2 and NF_3 , than liquid F_2 at 86 K (-187°C). The calculated XRD density of $(\text{NF}_4)_2\text{NiF}_6$ was 2.61 g/cm^3 . $(\text{NF}_4)_2\text{NiF}_6$ is a deep red hygroscopic solid that is stable at room temperature. In DSC it showed a very slow endothermic, irreversible decomposition between 383 and 403 K (110 and 130°C), which became rapid above 473 K (200°C). The rate constant of decomposition was

$$k = 4.840 \times 10^{14} \exp\left(\frac{E_{\text{act}}}{RT}\right)$$

$$E_{\text{act}} = 147 \frac{\text{kJ}}{\text{mol}} = 35.161 \frac{\text{kcal}}{\text{mol}}$$

The heat of formation of solid $(\text{NF}_4)_2\text{NiF}_6$ was estimated to be somewhere near or below -962 kJ/mol (-230 kcal/mol).

2.5.6 Tetrafluoroammonium Salts with Complex Group 13 Element Anions

Group 13 elements include B, Al, and Ga. Of all the anions NF_4^+ can be combined with to make a rocket propellant, BF_4^- is one of the most desirable due to its low molecular weight and the high heat of combustion of boron compounds [3]. The crystalline compound $\text{NF}_4^+\text{BF}_4^-$ has been prepared by exposing the heterogeneous ternary system $\text{NF}_3/\text{BF}_3/\text{F}_2$ to 3-MeV bremsstrahlung at 77 K. The compound is stable at room temperature in dry air. It decomposes above 523 K (250°C) to the reactants in a reversal of its formation reaction. It reacts rapidly with moisture and with organic substances. The ionic structure was confirmed by IR and Raman spectroscopy. The XRD powder pattern could be indexed on the basis of a tetragonal unit cell with $a = 7.01\text{ \AA}$ and $c = 5.22\text{ \AA}$.

Tetrafluoroammonium tetrafluoroborate, $\text{NF}_4^+\text{BF}_4^-$, is an important starting reagent for the preparation of other energetic oxidizers. One of the first steps in the preparation of NF_4BF_4 is the preparation of NF_4SbF_6 as an intermediate. For this purpose, NF_3 , F_2 , and SbF_5 in a 2:2:1 mol ratio are heated in a Monel cylinder to 523 K (250 °C) for 72 h. The size of the cylinder is chosen in such manner that at the completion of the reaction, the autogenous pressure is about 70 atm. The product is extracted from the Monel cylinder with anhydrous HF using about 50 mL of liquid HF per 100 g NF_4SbF_6 . NF_4BF_4 salt can be prepared either directly from NF_3 , F_2 , and BF_3 using glow discharge, bremsstrahlung, or UV, or indirectly from NF_4SbF_6 using a metathetical reaction. Of these, the metathetical process is the one most amenable to the larger-scale production of NF_4BF_4 utilizing existing technology. The original metathetical NF_4BF_4 process involved several steps but did not deliver a pure product. NF_4BF_4 of at least 97 mol-% purity can be prepared by a simpler process using anhydrous HF at different temperatures as the only solvent, and the last step of purification is the recrystallization from BrF_5 as the solvent [356].

NF_4BF_4 can be prepared by reaction of NF_4SbF_6 in 0–15 mol-% excess, with CsBF_4 in anhydrous HF [357]. NF_4SbF_6 in turn is prepared by heating SbF_5 in the presence of an excess of NF_3 and F_2 to 250 °C until conversion of the SbF_5 to NF_4SbF_6 is complete.

A very clean method for preparation of NF_4BF_4 and other NF_4^+ salts is by UV illumination at low temperatures. It was found that low-temperature UV photolysis is ideally suited for preparing NF_4BF_4 . A large number of reaction parameters were studied to maximize the yield [358]. Maximum yields of NF_4BF_4 were obtained at close to boiling point of liquid nitrogen temperatures (77 K [–196 °C]) using unfiltered UV radiation, a short path length to avoid recombination of F atoms to molecular F_2 , and the periodic addition of fresh starting materials to the UV cell to avoid coating of the surface of the condensed reactants by solid NF_4BF_4 . The highest yield of NF_4BF_4 achieved to date with a 900-W mercury arc lamp was in excess of 3 g/h. The quantum yield for the formation of NF_4BF_4 at a rate of 3 g/h was only 0.015. Based on XRD measurements, the calculated density of solid NF_4BF_4 is 2.27 g/cm³. Three new NF_4^+ salts, NF_4PF_6 , NF_4GeF_5 , and $(\text{NF}_4)_2\text{GeF}_6$, have also been prepared by UV photolysis and displacement reactions.

A controversy about the structure of the NF_4^+ cations in NF_4BF_4 could not be resolved based on vibrational spectra and XRD alone [359]. Only a redetermination of the crystal structure and solid-state ¹⁹F NMR spectra of NF_4BF_4 showed that, in accord with the vibrational spectra and contrary to a previously published crystal structure, the NF_4 cations in this salt are indeed tetrahedral [360]. These results resolved a long-standing controversy regarding vibrational spectroscopy and XRD crystallography.

The goal of the tetrafluoroammonium salt investigations was to come up with compounds with very high available fluorine content. The NF_4^+ salts derived from BeF_2 and AlF_3 would have a usable fluorine content of 71.7 and 69.3 mass-%, respectively, which is one of the best available. $\text{NF}_4\text{Be}_2\text{F}_5$ and NF_4AlF_4 were prepared from concentrated NF_4HF_2 solutions and BeF_2 and AlF_3 , respectively [361]. Tetrafluoroam-

monium tetrafluoroborate(III) is a hygroscopic white crystalline solid that is stable up to about 423 K (150 °C). It is highly soluble in anhydrous HF.

Both $(\text{NF}_4)_2\text{BeF}_4$ and $(\text{NF}_4)_3\text{AlF}_6$ have very high theoretical fluorine yields, but efforts to prepare these two compositions have been unsuccessful. Investigators succeeded partially in that NF_4AlF_4 and $\text{NF}_4\text{Be}_2\text{F}_5$ were prepared.

2.5.7 Tetrafluoroammonium Salts with Complex Group 14 Element Anions

Group 14 elements include Si, Ge, and Sn. Bis(tetrafluoroammonium) hexafluorosilicate(IV) can be made by reaction of tetrafluoroammonium hydrogen fluoride with tetrafluorosilicon [362]:

Bis(tetrafluoroammonium) hexafluorosilicate(IV) is a white crystalline solid that is stable at 298 K (25 °C) but slowly decomposes at 363 K (90 °C) to NF_3 , F_2 , and SiF_4 .

Bis(tetrafluoroammonium) pentafluorostannate(IV) $(\text{NF}_4)_2\text{SnF}_5$ can be prepared by a metathetical reaction between Cs_2SnF_6 and NF_4SbF_5 in HF solution [363]. It is a white solid and is stable at room temperature up to above 473 K (200 °C). Based on XRD, it crystallizes in the tetragonal system. Its composition was established by elemental analysis, and the presence of tetrahedral NF_4^+ and octahedral SnF_6^{2-} ions in the solid state and in BrF_5 solution was demonstrated by vibrational and ^{19}F NMR spectroscopy. The salt NF_4SnF_5 was obtained in quantitative yield from the displacement reaction between equimolar amounts of NF_4BF_4 and SnF_4 in HF solution. When a large excess of NF_4BF_4 was used, the main product was still the same NF_4SnF_5 , and only a small amount of $(\text{NF}_4)_2\text{SnF}_6$ was formed. The calculated XRD density of $(\text{NF}_4)_2\text{SnF}_6$ is 2.73 g/cm³. The NF_4SnF_5 salt was characterized by elemental analysis, vibrational and ^{19}F NMR spectroscopy, and XRD. The hydrolysis of $(\text{NF}_4)_2\text{SnF}_6$ and NF_4SnF_5 proceeds, as previously established for other NF_4^+ salts, with quantitative NF_3 evolution. This reaction can be used for elemental analysis of the compounds. An F_2 - NF_3 gas generator based on $(\text{NF}_4)_2\text{SnF}_6$ has the potential to form a self-clinkering residue in the combustion chamber and to produce very little dust.

2.5.8 Tetrafluoroammonium Salts with Complex Group 15 Element Anions

Group 15 elements include N, P, As, Sb, and Bi. Tetrafluoroammonium hexafluorophosphate, NF_4PF_6 , can be prepared by ultraviolet photolysis of a mixture of NF_3 , F_2 , and PF_5 at 77 K (−196 °C) [364].

Tetrafluoroammonium salts with more desirable anions can be prepared from the easy-to-obtain tetrafluoroborates through metathetical reactions if one of the products is insoluble or at least less soluble than the other. Tetrafluoroammonium hexafluorophosphate, NF_4PF_6 , can be prepared by a displacement reaction between NF_4BF_4 and PF_5 [365].

Tetrafluoronitrogen(V) hexafluoroarsenate(V), NF_4AsF_6 , can be prepared by reaction of NF_3 , AsF_5 , and F_2 in a 1:1:1 mol ratio in a glow discharge at low temperatures [320, 329]. It was the first tetrafluoroammonium salt to be discovered. This complex is considered a derivative of hypothetical NF_5 . The white crystalline powder is stable and non-volatile at 298 K (25 °C). Differential thermal analysis indicated incipient decomposition at about 543 K (270 °C). The compound was very hygroscopic and easily hydrolyzed to an initially pale blue solution with the evolution of gas. The XRD powder diffraction pattern could be indexed in the tetragonal system with unit cell dimensions $a = 7.70 \text{ \AA}$ and $c = 5.73 \text{ \AA}$.

NF_4AsF_6 has also been prepared by the glow discharge reaction of NF_3 , F_2 , and AsF_5 at 193 K (−80 °C) [366]. NF_4AsF_6 decomposed smoothly at 448 K (175 °C) and above to the starting materials NF_3 , F_2 , and AsF_5 [367, 368]. The decomposition has been followed by total pressure measurements and was found to obey the equation

$$P^{\frac{3}{2}} = At + B$$

This has been interpreted in terms of an equilibrium dissociation step

followed by irreversible decomposition of the unstable NF_5

The latter step was taken to be a 3/2-order reaction

$$\frac{dP}{dt} = k_1 P_n P_a$$

where P_n is the partial pressure of NF_5 and P_a that of AsF_5 . An attempt to identify NF_5 in the products by matrix isolation methods yielded, besides the expected NF_3 and AsF_5 , an unknown minor product that appeared not to contain any nitrogen.

Samples of both $^{14}\text{NF}_4\text{AsF}_6$ and $^{15}\text{NF}_4\text{AsF}_6$ were prepared by low-temperature UV-photolysis, and their vibrational spectra were recorded [369]. The observed spectra were in agreement with space group $P_{4/n}$ for NF_4AsF_6 and site symmetries of S_4 and C_4 , for NF_4^+ and AsF_6^- , respectively. The observed ^{14}N - ^{15}N isotopic shifts were used to compute a general valence force field for NF_4^+ .

Since most of the advanced NF_4 salts can be prepared from NF_4SbF_6 as a starting material, it was also important to simplify its synthesis as much as possible. The previous best synthesis involved the following two steps:

NF_4SbF_6 is prepared by heating SbF_5 in the presence of an excess of NF_3 and F_2 to 523 K (250 °C) until conversion of the SbF_5 to NF_4SbF_6 is complete [357]. This synthesis

was simplified to a one-step process according to [370]

Similar perfluoroantimonate complexes can be prepared starting with N_2F_4 instead of NF_3 (Section 3.3.2).

Tetrafluoroammonium hexafluoroantimonate(V) is a hygroscopic white crystalline solid that is stable up to about 543 K (270 °C). It is highly soluble in anhydrous HF (259 mg per gram of HF at 195 K [−78 °C]).

Tetrafluoroammonium hexafluorobismuthate(V) NF_4BiF_6 can be prepared by several methods, but depending on the method used, it may sometimes contain excess BiF_5 [371]. Similar to NF_4SbF_6 , it can be used for the synthesis of other NF_4^+ salts.

2.5.9 Tetrafluoroammonium Salts with Group 17 (Halogen) Anions

Ammonium perchlorate is the main oxidizer for solid propellants and some explosives. In an effort to increase the oxidizing power of AP, it has been attempted to replace the hydrogen in the ammonium ion by fluorine and, furthermore, to replace the oxygen in the perchlorate ion with fluorine as well. The result is tetrafluoroammonium tetrafluorochlorate NF_4ClF_4 , a stable compound and very powerful oxidizer.

Although the majority of tetrafluoroammonium salts are paired with fluoro complex anions, there are a few salts of interest that do not contain fluorine in the anion.

One of the salts of interest as a rocket propellant would be tetrafluoroammonium perchlorate, $\text{NF}_4^+\text{ClO}_4^-$, but it is very unstable. Its potential advantage is that it contains oxidizing groups both in the cation and in the anion. The same is true for tetrafluoroammonium nitrate, $\text{NF}_4^+\text{NO}_3^-$, but it has not yet been prepared [372].

The possibility of synthesizing NF_4XO_4 ($\text{X} = \text{Cl}, \text{Br}, \text{I}$) salts by metathetical reactions between NF_4SbF_6 , and CsXO_4 in anhydrous HF solution at 195 K (−78 °C) was studied [373]. Of these NF_4 salts, only $\text{NF}_4^+\text{ClO}_4^-$ was isolated and characterized by vibrational and ^{19}F NMR spectroscopy. $\text{NF}_4^+\text{ClO}_4^-$ is an unstable white solid decomposing at 298 K (25 °C) to give NF_3 and FOClO in high yield. If this chemical were used as an oxidizer in a cryogenic propellant, this would give a specific impulse much higher than any conventional solid propellant with ammonium perchlorate.

Other salts investigated were tetrafluoroammonium tetrafluorobromate $\text{NF}_4^+\text{BrF}_4^-$ and tetrafluoroammonium tetrafluorooxobromate $\text{NF}_4^+\text{BrF}_4\text{O}^-$ [374].

2.5.10 Tetrafluoroammonium Salts with Perfluoro Group 18 (Noble Gas) Anions

It is unlikely that salts of tetrafluoroammonium cation with noble gas anions would ever be used as rocket propellants, but we add them here just for speculation and curiosity. The perfluoroammonium salts of the heptafluoroxenon anions NF_4XeF_7 and $(\text{NF}_4)_2\text{XeF}_8$ can be prepared by reacting NF_4HF_2 with XeF_6 and exposing NF_4XeF_7 to blue 4880 Å laser light. The NF_4XeF_7 salt was prepared from XeF_6 and NF_4HF_2 and was converted to $(\text{NF}_4)_2\text{XeF}_8$ by selective laser photolysis. These new salts and the

already known CsXeF_7 and CsXeF_8 were characterized, and their vibrational spectra were reported. Evidence was presented for the existence of a stable NaXeF_7 salt [375–377], but it is doubtful that it can ever be used as a rocket propellant or gas generant for chemical lasers due to the limited availability of xenon (although much xenon is now used in ion and Hall thrusters). Irradiating the yellow NF_4XeF_7 with blue 4880 Å light causes disproportionation:

NF_4XeF_7 is of particular interest due to its exceptionally high energy content. The thermal decomposition of NF_4XeF_7 proceeds according to

The decomposition enthalpy of $\text{NF}_4\text{XeF}_7(\text{S})$ is $\Delta H_{\text{dec}} = 64.6 \pm 5 \text{ kJ/mol}$, and the enthalpy of formation is -490.7 kJ/mol [378]. A comparison of this value with those previously found for a series of NF_4^+ salts containing other complex fluoro anions showed that NF_4XeF_7 is by far the most energetic of these salts.

3 Tetrafluorohydrazine

Tetrafluorohydrazine, also known as N_2F_4 , F_2NNF_2 , 1,1,2,2-tetrafluorohydrazine, tetrafluorohydrazine, dinitrogen tetrafluoride, perfluorohydrazine, CAS RN [10036-47-2] is a colorless gas with a very unpleasant, fluorine-like odor. It is more reactive than NF_3 . With a formula weight of 104.01, it contains 73.06 mass-% F and 26.94 mass-% N. Nitrogen fluorides containing several nitrogen atoms in the molecule are difficult to synthesize and were not evaluated as rocket propellants until the mid-1960s.

3.1 Preparation of Tetrafluorohydrazine

Tetrafluorohydrazine was first prepared by reduction of NF_3 with metals at 573–773 K (300–500 °C) [204, 379]:

Me: 1 equivalent metal

Iron, copper, arsenic, antimony, and bismuth have been tested as the reducing metals. The yield can be up to 62% (based on the consumption of NF_3). The reaction of NF_3 with As, Sb, Bi, or Cu can be carried out in a fluidized bed or packed-bed reactor [380].

During the reaction of NF_3 with arsenic to produce N_2F_4 , small amounts of difluoroamine were obtained as by-product and identified by its mass spectrum and IR spectrum [381].

Instead of using metals, NF_3 can also be reacted with carbon to produce N_2F_4 [382, 383]:

If the reaction is carried out with activated charcoal dust in a fluidized bed, the contact time can be shortened from several minutes to 3 s at 673–773 K (400–500 °C). The N_2F_4 yield is up to 75% at a 75% NF_3 conversion. Hexafluoroethane is a by-product.

The controlled direct fluorination of ammonia with diluted fluorine in a copper tube can be modified by suitable adjustment of the mixture ratio to yield 11% N_2F_4 (based on F_2 consumption) [71]. Attempts to fluorinate $\text{N}_2\text{H}_4 \cdot 2\text{HF}$ with BrF_3 or BrF_5 were not successful [62]. Traces of N_2F_4 can be found as by-products if one adds BF_3 , AlF_3 , or PF_3 to the molten NH_4HF_2 electrolyte during the conventional NF_3 production [384].

Reaction of NF_3 with mercury at low pressure in a glow discharge leads to formation of N_2F_2 and N_2F_4 , which can then be adsorbed on silica gel and then separated by preparative gas chromatography [385, 386]. Instead of excitation in a glow discharge, the thermal reaction of NF_3 with mercury at 593–603 K (320–330 °C) leads also to N_2F_4 [387]. Small amounts of N_2F_4 are formed during the thermal decomposition of difluoroamine, a very unstable compound.

A mixture of N_2F_4 and NOF is obtained if one passes a mixture of NF_3 , NO , and/or N_2O through a nickel tube at high temperature [388, 389]. Tetrafluorohydrazine can be obtained by hydrolysis of *N,N*-difluorourea [390].

Very pure samples of N_2F_4 can be obtained by preparative gas chromatography [391]. These high-purity samples are suitable to determine physical and spectroscopic properties.

A continuous method for separation of N_2F_4 or NF_3 from carbon-containing contaminants is based on column absorption of the organic compounds in a trickle tower fed with chilled chloroform or tetrachloromethane [108]. The less soluble N_2F_4 accumulates in the gas phase. After the first pass, the N_2F_4 concentration can be 88% and can be improved by repeated passage through a trickle tower.

The application of N_2F_4 as a rocket propellant has been slowed by its high price and limited availability [392]. In the United States, Air Products Inc. has been supplying NF_3 and N_2F_4 since the 1960s.

Tetrafluorohydrazine can be synthesized from NF_3 using iron powder at a temperature of 673 K (400 °C) [393]. Iron(II) fluoride, as reducing agent, showed similar results in synthesizing N_2F_4 from NF_3 . The reaction of ClF_3 or ClF_5 with fluoroamine produced a 1 : 1 mixture of N_2F_4 and ClNF_2 [394].

A process based on the oxidation of difluoroamine by ferric ion was developed for the preparation of tetrafluorohydrazine and for pilot-plant scale-up [395]. Difluoroamine, made by hydrolysis of aqueous difluorourea, was passed through aqueous ferric chloride to effect the oxidation, and the product was passed through aqueous caustic to eliminate carbon dioxide, through aqueous ferrous chloride to remove nitric

oxide, and finally through Drierite to remove water. Only minor amounts of impurities remained in the product.

The process for the continuous production of N_2F_4 by the oxidation of HNF_2 by aqueous ferric ions was demonstrated on a pilot-plant scale [396]. The reactions were carried out at low pressures (34–103 kPa [5–15 psig]) and moderate temperatures (294–373 K [70–220 °F]), which facilitated system design and operation. Purification of the product was accomplished without cryogenic fractionation. Production rates of 0.8 kg/h (1.8 lb/h) with 98.5% pure N_2F_4 were routine. Scale-up of this process to much higher production rates appeared to be safe and technically feasible.

Several synthesis methods for N_2F_4 depend on the availability of difluorourea that can be made by direct fluorination of urea [397–399].

The reaction of NF_3 with elemental silicon, similar to reactions with carbon or certain metals, reduces NF_3 to NF_2 , which then recombines to N_2F_4 [400]. In the reaction products, the N_2F_4 has to be separated from SiF_4 by a series of wash baths and cold traps.

3.2 Physical Properties of Tetrafluorohydrazine

Some physicochemical constants of tetrafluorohydrazine (vapor pressure variation with temperature, normal boiling point, melting point, critical temperature and pressure, and heat of vaporization measurements between 112 and 306 K [–161 and +33 °C]) were measured and are considered the most reliable data at this time [401]. See also [8, 13, 130].

3.2.1 Freezing Point, Boiling Point, and Phase Diagrams of Tetrafluorohydrazine

The physical properties of tetrafluorohydrazine are summarized in Table 15, 16, and 17.

Table 15: Physical properties of tetrafluorohydrazine.

Property	SI units	MKS units	References
Molecular mass	104.0070		[132]
Boiling point	199 K	–74.1 °C	
Boiling point	198.9 ± 0.1 K	–74.2 ± 0.1 °C	[401]
Melting point (triple point)	104 K	–169 °C	
Melting point	111.6 ± 0.5 K	–161.5 ± 0.5 °C	[401]
Density, liquid, ρ (at 200 K [–73 °C])		1.652 g/cm ³	
Critical-point data			
$t_{\text{crit.}}$	309 K	+36 °C	
$t_{\text{crit.}}$	309.3 ± 0.1 K	+36.2 ± 0.1 °C	[401]
$P_{\text{crit.}}$	7.77 MPa	77 atm	
P_{crit}	3.70 ± 0.08 MPa	36.6 ± 0.8 atm	[401]

3.2.2 Vapor Pressure of Tetrafluorohydrazine

The vapor pressure of N_2F_4 can be represented by the following equations, one dating back to 1958 [204]:

$$\log p = 6.33 - \frac{692}{T}$$

where p is the pressure in mm Hg and T is the temperature in kelvin. The other dates to 1962 [391]:

$$\log p_V = 7.2163 - \frac{862.9}{T}$$

where p_V is the vapor pressure in mm Hg and T is the temperature in kelvin. See also Figure 4.

Figure 4: Vapor pressure of tetrafluorohydrazine. (Reprinted and modified from [391], with permission from © 1962 Elsevier; permission conveyed through RightsLink.)

More recent measurements gave the following equations to calculate the vapor pressure, one for the range between the triple point and the normal boiling point, and another for the range between the boiling point and the critical point, with accuracies from 1.25 to 1.5% [401]. Between the triple point and normal boiling point:

$$\log p_V = 7.0051 - 820.75/T$$

Between the boiling point and critical point:

$$\log p_V = 7.1950 - 861.57/T$$

where p_V is the vapor pressure in mm Hg and T is the temperature in kelvin.

3.2.3 Viscosity of Tetrafluorohydrazine

The viscosity of tetrafluorohydrazine as a liquid under pressure is 0.002 N s m^{-2} at 311.4 K (0.20 cPs at -38.3°C).

3.2.4 Thermal Conductivity of Tetrafluorohydrazine

The thermal conductivity of gaseous tetrafluorohydrazine is $0.150 \text{ W m}^{-1} \text{ K}^{-1} = 3.6 \times 10^{-4} \text{ cal s}^{-1} \text{ cm}^{-1} ^\circ\text{C}^{-1}$.

3.2.5 Solubility, Miscibility, Mixtures, and Solutions of Tetrafluorohydrazine

Liquid N_2F_4 in a molar ratio of 1:1 is completely miscible with CF_3Cl at 110 K or CCl_2F_2 at 130 K, but it forms two separate layers with O_2F_2 at 130 K [134].

A Henry's law constant of $0.00085 \text{ mol kg}^{-1} \text{ bar}^{-1}$ for the solubility of N_2F_4 in water that was shown in the NIST Chemistry WebBook is most certainly useless because N_2F_4 hydrolyzes in water and would not remain dissolved unreacted for any length of time.

3.2.6 Thermodynamic Properties of Tetrafluorohydrazine

Thermodynamic properties of tetrafluorohydrazine reported in the literature vary over a wide range, and it is difficult to decide which data are the most reliable. It is unclear whether the discrepancies were caused by insufficient purity of the samples, by deficiencies in the measurement techniques, or both. In some cases the sources – all second-hand sources – even failed to specify whether the data were for gaseous or liquid N_2F_4 . That lack of accuracy adds to the confusion. Most sources list only the enthalpy of formation of the gas, but if we were planning to use N_2F_4 as a liquid rocket propellant, then we would need the enthalpy of formation of the liquid the way it is stored in the propellant tank.

Table 16: Thermodynamic properties of tetrafluorohydrazine.

Property	SI units	Other units	References
Standard enthalpy of formation, gas (ΔH) ₂₉₈	-8.3 ± 10 kJ/mol	-2.0 ± 2.5 kcal/mol	[402]

Standard entropy of formation, gas (ΔH) ₂₉₈	301.18 J K ⁻¹ mol ⁻¹		[132]

3.2.6.1 Heat Capacity of Tetrafluorohydrazine

The heat capacity of gaseous N₂F₄ as a function of temperature can be calculated from the Shomate equation:

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + \frac{E}{\tau^2}$$

where C_p is the molar heat capacity in J mol⁻¹ K⁻¹; A, B, C, D, and E are constants; and τ is the absolute temperature in kelvin divided by 1000. The coefficients are listed in Table 17. The same coefficients (and others) are used for formulas expressing the standard enthalpy of formation and the standard entropy of the vapor. These equations were curve-fitted from data covering ranges from 298 to 1000 K and from 1000 to 6000 K.

3.2.6.2 Enthalpy of Formation of Tetrafluorohydrazine

The vapor-phase excess enthalpy above the standard enthalpy of formation $\Delta H^\circ_{f,298}$ of N₂F₄ can be calculated from the Shomate equation:

$$H^\circ - H^\circ_{298.15} = A\tau + \frac{B\tau^2}{2} + \frac{C\tau^3}{3} + \frac{D\tau^4}{4} - \frac{E}{\tau} + F - \Delta H^\circ_{f,298}$$

Table 17: Constants for vapor-phase thermodynamic properties of tetrafluorohydrazine.

Temperature range, K	298–1100	1100–6000
A	39.04848	132.1588
B	224.5360	0.488239
C	–205.0875	–0.098902
D	66.64526	0.006853
E	–0.925509	–8.286706
F	–31.41933	–71.53427
G	284.8057	424.8936
H	–8.368001	–8.368001

Data source: [132]

where A, B, C, D, E, and F are constants and τ is the absolute temperature in K divided by 1000. The coefficients are the same as those listed in Table 17. The same coefficients (and others) were used for a formula expressing the molar heat capacity of the vapor (Section 3.2.6.1). These equations were curve-fitted from data covering a range from 298 to 6000 K.

A calorimetric method was used to determine the enthalpies of formation ΔH°_{f298} of several nitrogen fluorides, based on their reaction with aqueous KI solutions in a calorimeter in which the gases were bubbled through the liquid [139]. The values of ΔH°_{f298} recommended for N_2F_4 were listed, although it was cautioned that the values for N_2F_4 were uncertain, with the need for further experimental verification.

Literature values for the enthalpy and entropy of formation of N_2F_4 and other nitrogen fluorides were collected and summarized, and expressions were derived for the temperature dependence of the free energy of formation of these substances [141]. The thermodynamics of several reactions for the synthesis of N_2F_4 involving the substances listed above were also examined.

The equilibrium dissociation of tetrafluorohydrazine via the reaction

has been studied behind incident shock waves over the temperature range 375–1500 K [209]. At temperatures above 500 K, the N_2F_4 is completely dissociated, and absorption measurements in this region yielded the absorptivity of $\bullet NF_2$ as a function of temperature. Absorption measurements in the temperature range 375–462 K yielded equilibrium constants for the above reaction. On the basis of second-law and third-law analyses of the data, a value of 87.4 ± 1.7 kJ/mol (20.9 ± 0.4 kcal/mol) for the heat of dissociation of N_2F_4 was obtained. In addition, previously reported measurements of the equilibrium constants for the reaction

have been reanalyzed, and a value of $239 \pm 4 \text{ kJ/mol}$ ($57.2 \pm 1.0 \text{ kcal/mol}$) was obtained for the heat of dissociation of NF_3 . The above results were then used to obtain revised values for the heats of formation of $\text{N}_2\text{F}_4 \Delta H^\circ_f(\text{G}) = -22.2 \pm 5.9 \text{ kJ/mol}$ ($-5.3 \pm 1.4 \text{ kcal/mol}$) and ${}^\bullet\text{NF}_2(\text{G}) = +32.6 \pm 4.2 \text{ kJ/mol}$ ($+7.8 \pm 1.0 \text{ kcal/mol}$).

3.2.6.3 Entropy of Tetrafluorohydrazine

The entropy of gaseous N_2F_4 at 298 K and 1 bar pressure is $S^\circ_{\text{gas}} = 301.18 \text{ J mol}^{-1} \text{ K}^{-1}$ (NIST Chemistry WebBook [132]). The entropy of gaseous N_2F_4 can be calculated from the polynomial equation

$$S^\circ = A \times \ln(\tau) + B \times \tau + \frac{C \times \tau^2}{2} + \frac{D \times \tau^3}{3} - E/(2 \times \tau^2) + G$$

where G is the integration constant in $\text{J mol}^{-1} \text{ K}^{-1}$, τ is the temperature in kelvin divided by 1000, and A , B , C , D , E , and G are constants listed in Table 17 for two different temperature ranges.

3.2.6.4 Heat of Dissociation of Tetrafluorohydrazine

The heat of dissociation of N_2F_4 into two ${}^\bullet\text{NF}_2$ free radicals is 83.2 kJ/mol (19.88 kcal/mol). Other sources (Evans and Tschuikow-Roux [405]) give $87.4 \pm 1.7 \text{ kJ/mol}$ ($20.9 \pm 0.4 \text{ kcal/mol}$).

3.2.7 Molecular Structure, Dipole Moment, and Molecular Orbital Calculations of Tetrafluorohydrazine

3.2.7.1 Molecular Structure of Tetrafluorohydrazine

The molecular structure of tetrafluorohydrazine F_2NNF_2 resembles that of hydrazine H_2NNH_2 . In the temperature range 123–193 K, the staggered (C_{2h}) and gauche (C_2) isomers of dinitrogen tetrafluoride are in equilibrium with each other, both in the condensed phase and the vapor phase. The staggered conformation is favored by about 2 kJ/mol , and a barrier of 12.5 kJ/mol hinders the free rotation of the NF_2 groups.

The structures of the difluoroamino free radical and tetrafluorohydrazine have been determined by electron diffraction [410]. The bond distances and bond angles determined by this method were as follows: $\text{N}-\text{F} = 1.363 \pm 0.008 \text{ \AA}$ and $\angle \text{FNF} = 102.5 \pm 0.9^\circ$ for NF_2 and $\text{N}-\text{F} = 1.393 \pm 0.008 \text{ \AA}$, $\text{N}-\text{N} = 1.53 \pm 0.02 \text{ \AA}$ and $\angle \text{FNF} = 103.7 \pm 0.9^\circ$ for F_2NNF_2 . The dihedral angle is considerably less in N_2F_4 than in N_2H_4 .

The far IR ($60\text{--}350 \text{ cm}^{-1}$) and low-frequency Raman ($80\text{--}150 \text{ cm}^{-1}$) spectra of gaseous N_2F_4 revealed the fundamental vibrations and several excited state transitions of the torsional mode of the *gauche* conformer [411]. Variable-temperature ($213\text{--}183 \text{ K}$ [-60 to -90°C]) studies of the IR spectra of N_2F_4 dissolved in liquid xenon provided data from which the enthalpy difference could be determined to be $69 \pm 6 \text{ cm}^{-1}$ ($824 \pm 71 \text{ J/mol} = 197 \pm 17 \text{ cal/mol}$), with the *trans* conformer the more stable rotamer. *Ab initio* calculations were then carried out with several different basis

sets, from which the structural parameters, conformational stability, harmonic force constants, and IR and Raman spectra could be predicted and compared to the experimental values when appropriate. Some of the fundamentals had to be reassigned, and the potential function governing the conformer interchange has been determined.

3.2.7.2 Bond Lengths and Bond Energies of Tetrafluorohydrazine Molecule

Under conditions that prevail in the ionization section of mass spectrometers, dinitrogen tetrafluoride will be totally dissociated [412]. The dissociation energy was estimated as 80.3 kJ/mol (19.2 kcal/mol).

Bond dissociation energies of N_2F_4 and other molecules determined by kinetic methods were summarized in [413].

The interatomic distances, bond angles, and the proportions of *gauche* and *trans* isomers present in N_2F_4 have been determined by gas-phase electron diffraction [414]. The two rotamers are similar in structure except for the dihedral angle of $67.1 \pm 0.8^\circ$. The 47% *gauche*-53% *trans* mixture found at below room temperature indicated that the *trans* configuration is 1255–2092 J (300–500 cal) more stable than the *gauche* rotamer. The bond lengths N–N of $1.489 \pm 0.007 \text{ \AA}$ and N–F $1.375 \pm 0.004 \text{ \AA}$ are the same for both species, but the valence angles are slightly different ($\angle \text{FNF}$ *gauche* is $105.1 \pm 1^\circ$, $\angle \text{FNF}$ *trans* is $102.9 \pm 0.75^\circ$, $\angle \text{F}_1\text{NN}$ *gauche* is $100.1 \pm 1.0^\circ$, $\angle \text{F}_2\text{NN}$ *gauche* is $104.3 \pm 1.0^\circ$, $\angle \text{FNN}$ *trans* is $100.6 \pm 0.8^\circ$). The non-bonded mean-square amplitudes showed a strong angular dependence on the equilibrium geometry due to torsional motion about the N–N bond.

Analysis of electron-diffraction patterns from gaseous N_2F_4 at 298 K (25°C) has verified conclusions from earlier work that the material contains both *trans* and *gauche* conformers [415]. Assuming that these conformers have the same parameter values except for the torsion angle, the following principal results were obtained: 71.2 $\pm$ 8.1% *trans* configuration, $r_{\text{N}-\text{N}} = 1.492 \pm 0.007 \text{ \AA}$, $r_{\text{N}-\text{F}} = 1.372 \pm 0.002 \text{ \AA}$, $\angle \text{FNF} = 103.1 \pm 0.6^\circ$, $\angle \text{NNF} = 101.4 \pm 0.4^\circ$, θ (the dihedral angle $\angle \text{N}_2\text{N}_1\text{F}_4$, $\angle \text{N}_1\text{N}_2\text{F}_1 = 64.2 \pm 3.7^\circ$). The electron diffraction results indicated that the energy difference $E_{\text{gauche}} - E_{\text{trans}}$ is roughly less than 1.0 kcal but that the rotational barrier may be several kilocalories.

3.2.7.3 Dipole Moment of Tetrafluorohydrazine

The intrinsic moment of the N–F bond in N_2F_4 is 1.29 D, whereas it is 1.24 or 1.60 D in NF_3 [198].

3.2.7.4 Molecular Orbital Calculations of Tetrafluorohydrazine Molecule

Results from several *ab initio* method calculations were compared with local, hybrid, and gradient-corrected DFT methods for computing structures and energies of N_2F_4 rotamers [416]. The generated energies of *trans*- and *gauche*- N_2F_4 rotamers and their

dissociation energies to $\bullet\text{NF}_2$ free radicals were compared with experimental data. Suitable hybrid and gradient-corrected DFT methods for determining structures and energies for these and similar molecular systems were discussed.

3.2.8 Optical Properties of Tetrafluorohydrazine

3.2.8.1 Infrared Absorption Spectra of Tetrafluorohydrazine

The IR spectrum of N_2F_4 (Figure 5) can be used to calculate N—F and N—N bond strengths and determine the molecule conformation. Similar to hydrazine, there exists free rotation around the N—N axis at temperatures above 300 K. Recording the IR spectrum was complicated by reaction of N_2F_4 with the NaCl windows of the sample cell [391].

Figure 5: IR spectrum of tetrafluorohydrazine. (Reprinted and modified from [391], with permission from © 1962 Elsevier; permission conveyed through RightsLink.)

Because they are always in equilibrium with each other, it would be difficult to separate the IR spectra of N_2F_4 and $\bullet\text{NF}_2$, except the former dominates at low temperatures and the latter prevails at high temperatures [417]. When equilibrium mixtures of N_2F_4 and NF_2 are heated in a conventional IR cell to increase the proportion of NF_2 , profound changes in the IR spectrum are observed. The 1010 cm^{-1} band of N_2F_4 is found to decrease drastically, while smaller decreases are found at 960 and 740 cm^{-1} . A large increase is found between 940 and 910 cm^{-1} , with smaller increases at 990 – 970 and 735 – 730 cm^{-1} . It is not possible to distinguish the bands, however, because of severe overlapping by N_2F_4 bands at 1010 , 960 , and 735 cm^{-1} . To increase the resolution of the NF_2 spectrum, a compensating technique was used to cancel the N_2F_4 spectrum. A short cell (2 cm) was filled to a high pressure of N_2F_4 and placed in the reference beam, and a long cell filled to a low pressure was placed in the sample beam.

A complete vibrational analysis of the IR spectrum of N_2F_4 was carried out on the assumption that the molecule belongs to the point group C_2 [418]. The 12 normal vibrations of this point group have been assigned to observed bands. The band due

to the torsional vibration was observed at 122 cm^{-1} in the far-IR spectrum of the vapor. The band contours were consistent with a dihedral angle smaller than 90° .

When trying to identify bands in the $900\text{--}1000\text{ cm}^{-1}$ range of the IR absorption spectrum of N_2F_4 , it was assumed that N—F valency vibrations in N_2F_4 change in the same manner on transition from the gaseous to the solid state as those in NF_2Cl [419, 420]. Comparison of N_2F_4 spectra in the gaseous and solid states made it possible to isolate the following bands: **(1)** band with Q, P, and R branches and maxima at 934 , 911 , and 950 cm^{-1} , respectively; **(2)** with P and R branches, maxima at 950 and 965 cm^{-1} , respectively, and a minimum at 958 cm^{-1} ; **(3)** with P and R branches, maxima at 965 and 1010 cm^{-1} and a minimum at 1003 cm^{-1} ; and **(4)** with Q, P, and R branches and maxima at 1018 , 1010 , and 1034 cm^{-1} , respectively. The following correlation between fundamental frequencies of the IR spectrum of N_2F_4 at $120\text{--}1100\text{ cm}^{-1}$ and molecular vibrations was proposed on the basis of the experimental results obtained (frequency in cm^{-1}): 122 , $\text{F}_2\text{N--NF}_2$ rotational; 270 , NNF deformation; 379 , NNF deformation; 466 , NNF deformation; 517 , FNF deformation; 539 , FNF deformation; 587 , FNF deformation; 737 , N—N valency; 934 , NF symmetric valency; 859 , NF anti-symmetric valency; 1003 , anti-symmetric valency; and 1018 , symmetric valency. The normal vibration frequencies of N_2F_4 were calculated by using the same force constants for the NF_2 group as those that apply to this group in NF_2H , NF_2D , NF_2Cl , and NF_2Me molecules, giving satisfactory agreement between calculated and measured values.

The IR spectrum of liquid N_2F_4 at 153 K (-120°C) was found to be essentially identical to that of the solid and the vapor [421]. A comparison of these data with Raman results on the liquid indicated that a number of frequencies are mutually exclusive in the IR and Raman spectra. This was taken as evidence for the presence of the *trans* isomer in addition to the *gauche* one.

The IR spectrum of gaseous N_2F_4 was reanalyzed in the $4000\text{--}20\text{ cm}^{-1}$ region, and a number of new details on band positions and IR band contours were discovered [422]. The vibrational assignments, based on the new IR data and earlier reported Raman data, strongly supported the concept that N_2F_4 actually consists of an equilibrium mixture of two rotational isomers, *trans* (C_{2h}) and *gauche* N_2F_4 , differing very little in energy as suggested by NMR and electron diffraction data. The new vibrational assignment differed considerably from those offered in earlier investigations.

The IR spectra of N_2F_4 solutions in liquid argon and nitrogen have been recorded and reanalyzed in the $3300\text{--}3550\text{ cm}^{-1}$ region, and the fundamental absorption bands of NF-stretching modes of both the *gauche* and *trans* isomers and the bands of second-order transitions have been observed [423]. These IR data on the spectra of cryosystems and published Raman data allowed an unambiguous interpretation of the NF_2 -stretching vibrational bands for both the N_2F_4 conformers.

The far-IR ($60\text{--}350\text{ cm}^{-1}$) and low-frequency Raman ($80\text{--}150\text{ cm}^{-1}$) spectra of gaseous N_2F_4 revealed the fundamental vibrations and several excited-state transitions of the torsional mode of the *gauche* conformer [411].

IR spectra of N_2F_4 at higher temperatures are not those of the N_2F_4 molecule but those of the difluoroamino free radical $\cdot\text{NF}_2$ [424, 425]. IR spectra can be measured to determine the degree of dissociation of N_2F_4 as a function of temperature and pressure.

The decay of N_2F_4 in moist air was tracked by a sequence of IR spectra, as shown in Figure 6.

Raman Spectra of Tetrafluorohydrazine

The Raman spectra of liquid N_2F_4 at temperatures ranging from 193 to 123 K (-80 to -150°C) showed 17 pronounced Raman lines, whereas the C_2 isomer of N_2F_4 accounts for only 12 fundamentals [426]. The large number of Raman lines suggested the presence of more than one isomer at 153 K (-120°C). A comparison of the IR and Raman bands below 800 cm^{-1} showed that the mutual exclusion principle is operative, and it was concluded from this alternative forbiddenness that the *trans*- N_2F_4 isomer of C_{2h} symmetry gives rise to these mutually exclusive bands. Assignment of the observed frequencies based on depolarization values, band positions, and IR band contours were presented for the molecule in both the C_2 and C_{2h} configurations. It was shown that the data could be interpreted only in terms of an equilibrium mixture of the two isomers at both ambient and lower temperatures and that these isomers differ little in energy.

The Raman spectra of gaseous N_2F_4 at a pressure of 760 torr and of the solid at 18 K were recorded with a spectral slit width of 3 cm^{-1} [427]. Ten of the expected 11 fundamentals of the symmetric motions of both the *gauche* and *trans* rotamers gave rise to strongly polarized Raman lines. These new data required a reassignment of some of the fundamentals for both the C_2 and C_{2h} conformers. Both conformers were found in the solid even after annealing the sample for 9 h at a temperature of 101.6 K and for 3 h at a temperature of 106.8 K. Bands attributable to the *gauche* rotamer became more intense relative to those for the *trans* rotamer after several hours of annealing.

Microwave Spectra of Tetrafluorohydrazine

In the microwave spectrum of N_2F_4 , ten $J = 1$ lines with $J \leq 4$ have been assigned [428]. A number of Q-branch transitions at higher J numbers have also been identified.

The ground-state rotational microwave spectrum of *gauche*- N_2F_4 has been investigated between 8 and 200 GHz, including quantum states up to $J = 74$ and $K = 39$ [429]. Quadrupole coupling hyperfine structures were analyzed to give $\chi_{aa} = 2246(12)\text{ MHz}$ and $\chi_{cc} = -1792(5)\text{ MHz}$. The hypothetical ($e_Q = 0$) center frequencies were fitted using a rigid-rotor Hamiltonian function, including centrifugal-distortion terms up

to the eighth degree in (J , K). The rotational constants are $A = 55761995(1)$ MHz, $B = 318943277(8)$ MHz, and $C = 281316955(8)$ MHz. The electric dipole moment along the c axis was determined from field shifts of magic-doublet components to be $\mu_e = 0.256(4)$ D.

Ultraviolet Spectra of Tetrafluorohydrazine

In the course of flash-photolysis kinetic-spectroscopy experiments on NF-containing compounds, it was found necessary to examine the absorption of the NF_2 radical at 2600 Å at a higher dispersion than that used by previous authors [430].

An investigation of the photolysis of NF_2 was carried out by kinetic absorption spectroscopy in the UV vacuum [431]. A series of diffuse bands in the region of 126–140 nm were attributed to Rydberg transitions of NF_2 . A number of transient bands have also been observed and attributed to the species NF in more than one electronic state, and some collisional rate data for these bands were calculated.

3.2.9 Magnetic Properties of Tetrafluorohydrazine

When first measured, the ^{19}F nuclear magnetic resonance spectrum of tetrafluorohydrazine consisted of a single broad unresolved band at a field of approximately 75 ppm lower than that of the ^{19}F nuclei of trifluoroacetic acid [204]. Resolution of the expected triplet was not observed, probably because of the low symmetry of tetrafluorohydrazine.

The ^{19}F NMR spectrum of the *trans* and *gauche* rotamers of N_2F_4 was analyzed, and the *gauche* form was found to best be represented by the AA'BB' system [432]. The parameters of *gauche* N_2F_4 were $\delta = 688.6$ cps, $\text{JAB} \pm 489.6$ cps, $\text{JAB}' = \pm 13.4$ cps, $\text{JAA}' = \pm 58.8$ cps, and $\text{JBB}' = \pm 109.0$ cps.

3.3 Chemical Properties of Tetrafluorohydrazine

Tetrafluorohydrazine is a compound that easily decomposes similar to hydrogen peroxide or hydrazine. When the N_2F_4 gas is ignited with a hot wire, it decomposes completely to NF_3 and N_2 , but it usually does not detonate. Similar to NF_3 , N_2F_4 also dissolves in liquid OF_2 and is miscible with this oxidizer in all proportions. Such oxidizer mixtures might be useful as oxidizers for hydrocarbon fuels in rocket engines.

3.3.1 Reactions of Tetrafluorohydrazine

Tetrafluorohydrazine does not react hypergolically with most rocket fuels. It dissociates at room temperatures, and there are measurable numbers of NF_2 radicals similar to the dissociation of N_2O_4 .

3.3.1.1 N₂F₄ Reactions with Inorganic Compounds

Tetrafluorohydrazine will react with elemental fluorine and form NF₃ [433], but no higher nitrogen fluorides (NF₅?) were found [253, 254].

Reactions of N₂F₄ with O₃, O atoms, NO₂, or NO did not result in the formation of a more powerful oxidizer like the hoped-for, yet-unknown F₂NO₂ or F₂NOONF₂ [434]. The reactions of tetrafluorohydrazine with Cl₂O₇ or ClF₃ did not result in the formation of new oxidizers, either.

Many of the reactions initially attributed to N₂F₄ are actually reactions of the difluoroamino free radical formed by dissociation of N₂F₄ [435]. The physical and chemical properties of the difluoroamino radical have been determined separately and independently of the properties of tetrafluorohydrazine from which it was formed.

The rate of the exothermic free radical reaction

has been directly determined by measuring the disappearance of fluorine and the initial rate of NF₃ formation in the temperature range 1100–1600 K by means of a shock tube coupled to a TOF mass spectrometer [436]. The Arrhenius expression

$$k_a = 4.8 \times 10^9 \exp(-14400/RT) \frac{\text{mol}}{\text{s}}$$

was obtained for the rate constant, which when extrapolated ($\sim 10^7$) to near room temperature was in reasonable agreement with corrected data.

Reactions of N₂F₄ with Lewis acids resulted in the formation of a wide variety of trifluorodiazinium N₂F₃⁺ and pentafluorodiazinium N₂F₅⁺ salts, which are discussed in a separate section to follow.

Tetrafluorohydrazine is more reactive than NF₃ and will hydrolyze with water at room temperature. In moist air, it will decompose under formation of NO₂, NOF, HF, and N₂.

The reaction of dinitrogen tetrafluoride with aqueous solutions of potassium iodide varies with pH but is temperature independent [437].

The reaction of N₂F₄ with sodium azide at 318–358 K (45–85°C) produced NF₃, dinitrogen, and NaF [438]. The yield of NF₃ is pressure dependent and increases almost linearly from 30% at 3 atm to 70% at 8.5 atm. Two reactions occurred simultaneously and competitively; one produced NF₃, dinitrogen, and NaF, and the other yielded only dinitrogen and NaF.

The atmospheric decay of N₂F₄ was studied in preparation for animal-exposure toxicity tests with this material [439]. An IR study of the degradation of N₂F₄ in air was undertaken and is illustrated in Figure 6. The sequence of spectra confirm the course of reaction elucidated by Dost et al. [283, 440, 441]. Figure 6a is the pure N₂F₄ spectrum before the addition of air. Figure 6b is the spectrum 8 min after the addition of air and is essentially a spectrum of NOF with a small amount of N₂O₄. In Figure 6c, 24 min after air addition, the concentration of NOF has decreased and that of N₂O₄

Figure 6: IR spectra showing degradation of research-grade N_2F_4 in room air. (Reproduced from MacEwen [439].)

has increased. In addition, new peaks at 3.5, 5.8, and 5.9 microns indicate the possible production of HF and NOCl (possibly from reaction of NOF with the AgCl cell windows). In the last spectrum, Figure 6d, 60 min after air addition, NOF has almost completely disappeared, the cell containing mostly N_2O_4 and possibly HF and NOCl. The same series of reactions apparently occurred with propellant-grade N_2F_4 but at a much faster rate than with the research grade. For example, it took 60 min for complete conversion of research-grade N_2F_4 to N_2O_4 , whereas the same conversion took place in about 5 min with the propellant grade, although the degradation time was quite variable and seemed to be subject to many influences (Figure 7). The presence of NO in the propellant-grade N_2F_4 may account for the increase in reaction rate with air, since it is known that the following reaction takes place readily in air:

Figure 7: Degradation of research-grade N_2F_4 in room air. (Republished and modified from Dost et al. [284], with permission of © 1968 Elsevier Science Technology Journals; permission conveyed through Copyright Clearance Center Inc.)

Since both NF_2 and NO_2 are free radicals, they could combine briefly to form O_2NNF_2 , which then decomposes to NOF

When small amounts of NO_2 were added to dilute N_2F_4 in dry air or nitrogen, NO_2 disappeared rapidly, with a simultaneous decrease in N_2F_4 and an increase in NOF. Thus, NO would be catalytic for the degradation of N_2F_4 in air. The combined use of IR spectrophotometry, mass spectrometry, and gas chromatography led to the successful characterization of the impurities present in propellant-grade N_2F_4 that affected its degradation in air. This degradation occurred at a much faster rate with propellant-grade N_2F_4 than with the research grade, possibly due to the presence of NO in the former material. See also [442].

One of the shortcomings of tetrafluorohydrazine as a storable propellant in combination with hydrazine, ammonia, or MMH is the lack of hypergolicity. It was attempted to hypergolize N_2F_4 by the addition of N_2O_4 or ClF_5 [443]. N_2O_4 reacted spontaneously with N_2F_4 with a luminous flame and could therefore not be used as an additive. ClF_5 did not react spontaneously with N_2F_4 . Chlorine trifluoride was not used in this test series because it was known that it would react with N_2F_4 at higher temperatures, forming NF_3 and ClF in an exchange of fluorine atoms. At temperatures above 373 K (100 °C), ClF_5 and N_2F_4 also began to react, but the reaction products could not be identified. The most likely products of that reaction are ClF , ClF_3 , and NF_3 .

3.3.1.2 N₂F₄ Reactions with Organic Compounds

Reactions of N₂F₄ with alkanes, alkenes, and alkynes lead to difluoroamino compounds of the R—NF₂ type, which have been evaluated as monopropellants and energetic plasticizers for solid propellants:

Addition reactions of N₂F₄ have been described with olefins, acetylenes, allyl chloride, diallyl ether, cyclic olefins, vinyl alcohol, and many other organic compounds. There are too many reactions and a wide variety of organic —NF₂ compounds to include them all in this chapter, e.g., [444–446]. There are several other sections in this book describing organic —NF₂ compounds and their proposed uses as monopropellants, energetic plasticizers, and energetic binders.

Tetrafluorohydrazine reacts with acetylenes to produce α -fluoro- α -difluoroamino fluorimines. These compounds appear to be the result of a rearrangement of the original adduct, α,β -bis(difluoroamino)ethylenes [447].

If N₂F₄ was irradiated at 2537 Å in the presence of alkanes, the major process was substitution of a hydrogen atom by an NF₂ group, photodifluoramination, reminiscent of photochlorination. Similar treatment of alkenes and alkynes resulted in addition of the elements of NF₂ to the multiple bond. Kinetic and stoichiometric information about the photodifluoramination process was obtained from a study of the photolysis of NF₂ with methane. Irradiation of N₂F₄ with propylene and isobutylene resulted not only in substitution of NF₂ for H but also in addition of F and NF₂ to the double bond. The F was found mainly on the terminal carbon atom [448].

HF-stimulated emission has been observed from flash-photolyzed mixtures of N₂F₄ with a number of hydrogen sources: HCl, CH₄, CH₃F, CH₂F₂, CH₃Br, C₂H₆, C₂H₅F, and C₂H₅I [449].

Addition of N₂F₄ to alkenols or alkenyl esters gives bis(difluoroamino)alkanols, which can be nitrated to give difluoroamino-substituted alkyl nitrates, which are very energetic compounds [450].

3.3.2 Trifluorohydrazinium Salts Derived from Tetrafluorohydrazine

Similar to the large group of tetrafluoroammonium salts, there is a similar, less exhaustively examined group of salts derived from reaction of tetrafluorohydrazine with Lewis acids, such as SbF₅ or AsF₅.

The first reports on the formation of a stable adduct between N₂F₄ and a Lewis acid were published in 1965 and 1966 by Ruff [451, 452].

Boron trifluoride, which is a weaker Lewis acid than AsF₅ or SbF₅, did not form a stable adduct with N₂F₄ at temperatures as low as 195 K (–78 °C). Equimolar amounts of N₂F₄ and BF₃, when combined at 195 K (–78 °C) in a Teflon-FEP ampoule, did not form a solid. The liquid could be distilled at 195 K (–78 °C) to a colder trap without leaving any solid residue behind.

The reaction of tetrafluorohydrazine with arsenic(V) fluoride at 195 K (-78°C) produced a solid salt that was analyzed by IR, but it decomposed after a few days of storage under dry nitrogen at room temperature [453].

SbF_5 , when treated with an excess of N_2F_4 , produced either the 1:2 adduct $\text{N}_2\text{F}_4 \cdot 2\text{SbF}_5$ or the 1:3 adduct $\text{N}_2\text{F}_4 \cdot 3\text{SbF}_5$. The IR spectra from 4000 to 250 cm^{-1} and laser Raman spectra of solid $\text{N}_2\text{F}_3\text{AsF}_6$ and $\text{N}_2\text{F}_3\text{Sb}_2\text{F}_{11}$ were measured to study the molecular structure and compare it to crystal structure information obtained from XRD [454]. N_2F_4 and SbF_5 reacted in anhydrous HF to produce $\text{N}_2\text{F}_3\text{SbF}_6$ [455, 456]. The reaction between N_2F_4 and AsF_5 can be achieved at room temperature quantitatively even without HF solvent. These salts are useful as a burn-rate modifier in NF_3 - F_2 gas generators. Trifluorohydrazinium pentafluorostannate $\text{N}_2\text{F}_3\text{SnF}_5$ is formed by reacting $\text{N}_2\text{F}_3\text{SbF}_6$ and Cs_2SnF_6 in the presence of HF as a solvent [341]. $\text{N}_2\text{F}_3\text{SnF}_5$ is useful as a component of NF_3 - F_2 gas-generating compositions.

3.3.2.1 Other Salts Derived from Tetrafluorohydrazine

The purported synthesis of $\text{N}_2\text{F}_5^+(\text{CF}_3)_3\text{CO}^-$, a salt containing the unknown pentafluorohydrazinium cation, would have been the first known example of a substituted NF_4^+ cation, i.e. an NF_4^+ cation in which a fluorine ligand is replaced by an NF_2 group [457]. Since such a heterolytic fission of $(\text{CF}_3)_3\text{COF}$ with F^+ formation is unlikely, the reported synthetic and spectroscopic evidence for $\text{N}_2\text{F}_5^+(\text{CF}_3)_3\text{CO}^-$ was critically reviewed [458]. The reexamination indicated that the reported white solid was not $\text{N}_2\text{F}_5^+(\text{CF}_3)_3\text{CO}^-$ but was most likely the known compound $(\text{NO}^+)_2\text{SiF}_6^{2-}$.

3.3.3 Analysis of Tetrafluorohydrazine

For the analysis of tetrafluorohydrazine in air, the compound was converted to fluoride ion by nitrogen dioxide and water [459]. The fluoride ion was detected continuously in a flow-through apparatus by a commercial fluoride ion electrode. A 30-mV change in electrode potential was obtained for 1 part per million of N_2F_4 in the air. Various factors affecting sensitivity, stability, interferences, and speed of the detection system were considered.

3.3.3.1 Mass Spectrometric Analysis of Tetrafluorohydrazine

The fragmentation process producing NF_2^+ is complex, and several pathways for its production have been proposed, based on the relative abundance of ions in the mass spectrum with an excitation voltage of 70 eV. It was the second most abundant ion after NF^+ . The ionization potential of NF_2 was calculated as 11.4 V [460].

Mass spectra and appearance potentials for dinitrogen tetrafluoride and its dissociation products NF_2 , NF_3 , and N_2F_2 were measured, and the activation energy of the dissociation reaction was determined from an Arrhenius plot [461, 462].

Appearance potentials have been measured for selected ions from NF_2 , NF_3 , N_2F_2 , and N_2F_4 [463]. Ionization-dissociation processes were identified, and bond dissociation

tion energies were calculated. The N—N bond dissociation energy, $D(\text{F}_2\text{N}-\text{NF}_2)$, was directly measured to be $5.14 \pm 0.38 \text{ kJ/mol}$ ($21.5 \pm 1.6 \text{ kcal/mol}$). The appearance potential of N_2F_4 was $12.0 \pm 0.1 \text{ eV}$.

During attempts to analyze N_2F_4 by mass spectrometry, reactive species often react prematurely in the inlet to a mass spectrometer before a clean mass spectrum can be obtained. Cooling the mass spectrometer inlet to 83 K (-190°C) will allow the sample to enter the ionization chamber unadulterated. Mass spectra of N_2F_4 and several other reactive fluorides were obtained by this method [464]. Operating at low temperatures will also allow one to examine the sample for dimer association in the vapor phase. The appearance potential of NF_2^+ from N_2F_4 was 12.63 eV .

3.3.3.2 Gas Chromatographic Analysis of Tetrafluorohydrazine

Tetrafluorohydrazine can be purified by preparative gas chromatography. In particular, it is important for this purification method to remove C_2F_6 , a contaminant that is otherwise difficult to remove [391].

Tetrafluorohydrazine can be analyzed by gas chromatography and IR spectrophotometry [465].

Mixtures of F_2 , HF , NF_3 , *trans*- N_2F_2 , and N_2F_4 can be analyzed by gas chromatography [266].

3.4 Thermal Decomposition and Radiolysis of Tetrafluorohydrazine

3.4.1 Thermal Decomposition of Tetrafluorohydrazine

The NF_2 free radical is formed not only as a result of photolysis of N_2F_4 but also as the result of simple thermolysis, i.e., thermal dissociation of N_2F_4 .

The enthalpy and entropy changes of the N_2F_4 dissociation were measured between 373 and 423 K by two independent methods, one a constant-volume pressure measurement and the other a spectroscopic method [466, 467]. The constant-volume method gave $\Delta H = 83.3 \text{ kJ/mol} = 19.9 \text{ kcal/mol}$ and $\Delta S = 39.9 \text{ e.u.}$ The spectroscopic method gave $\Delta H = 90.8 \text{ kJ/mol} = 21.7 \text{ kcal/mol}$ and $\Delta S = 45.0 \text{ e.u.}$

The EPR spectrum of the difluoroamino radical ($^*\text{NF}_2$) was observed as a function of temperature and found to be a single broad line at a pressure of $2.67\text{--}5.33 \text{ kPa}$ ($20\text{--}40 \text{ mm Hg}$) of N_2F_4 and a temperature of $340\text{--}435 \text{ K}$. The constant-volume dissociation energy of N_2F_4 was obtained directly from the slope of an Arrhenius plot and was 78.2 kJ/mol (18.7 kcal/mol). The enthalpy change ΔH was found to be 80.7 kJ/mol (19.3 kcal/mol). The N—N bond strength in N_2F_4 was evaluated by three methods, and the best value for the heat of dissociation of N_2F_4 was 82.8 kJ/mol ($19.8 \pm 0.8 \text{ kcal/mol}$) [468, 469]. The IR spectra and thermodynamic properties of $^*\text{NF}_2$ were measured, and the energy levels of the fragment and its electron orbitals were calculated from molecular orbital theories [425, 470].

The EPR spectrum of NF_2 was observed in the gas phase at approximately 40 mmHg pressure and over the temperature range 340–435 K [471]. The spectrum observed was a single broad line with a g -value of 2.010 and a peak-to-peak line width of 104 gauss. The spectrum of NF_2 in a matrix of solid argon showed some hyperfine structure, in particular, a center triplet arising from interaction with the ^{14}N nucleus (16 gauss) and corresponding to the NF_2 spin state in which the two fluorine nuclei spins are anti-parallel. Two side lines were also found about 47 gauss from the center line.

Difluoroamino radicals ($\cdot\text{NF}_2$) formed during dissociation of N_2F_4 can be trapped and stabilized on molecular sieves for further examination by EPR [472]. The other technique is to trap them in a solid matrix of frozen argon or neon at liquid helium temperatures [473].

The rate of dissociation of N_2F_4 in N_2 and Ar was determined at temperatures between 344 and 410 K and total pressures between 0.6 and 6.0 atm in a shock tube [474, 475]. The progress of the reaction behind the incident shock wave was followed by a time-resolved spectrophotometric technique. The absorption coefficient of NF_2 at $12602\text{ \AA}$ was determined between 350 and 571 K and found to be $537 \pm 10\text{ L mol}^{-1}\text{ cm}^{-1}$. The kinetics data indicated that the dissociation in 99% N_2 was quasi-unimolecular throughout the experimental pressure range, attaining its first-order limit at a total pressure not far above 6 atm and its second-order region below 0.6 atm. The observed pressure for the region of transition from first-order to second-order kinetics was reasonably consistent with the transition pressure obtained from classical theory on the basis of the estimated value ($2 \times 10^{15}\text{ s}^{-1}$) of the pre-exponential factor for the limiting high-pressure first-order specific rate. At approximately 2 atm, the observed specific rate for the nitrogen mixture was given by

$$k_2(\text{N}_2) = 10^{14.98} \pm 0.42 \exp \left[\left(-19.4 \pm 0.7 \frac{\text{kcal}}{\text{mol}} \right) / RT \right] \text{ s}^{-1}$$

between 344 and 407 K.

The equilibrium dissociation of $\text{N}_2\text{F}_4 \rightleftharpoons 2\text{NF}_2$ was studied in shock waves, yielding an equilibrium constant identical to those obtained previously in static measurements [476]. The thermal dissociation rate for N_2F_4 diluted with argon, helium, or SF_6 was studied between 523 and 623 K (350 and 450 °C) at total pressures of 0.058–0.27 MPa (0.58–2.7 atm). The reaction

was found to be first order in M and first order in N_2F_4 , indicating a bimolecular mechanism. The rate constant k_{Ar} for argon dilution could be expressed either by

$$k_{\text{Ar}} = 1.5 \times 10^{12} T^{0.5} \exp(-15200/RT)$$

or

$$k_{Ar} = 2.96 \times 10^8 T^{0.5} \left(\frac{E_0}{RT} \right)^{4.0} \exp \left(-\frac{E_0}{RT} \right)$$

where k_{Ar} is the rate constant in $\text{L mol}^{-1} \text{s}^{-1}$, T is the temperature in kelvin, and E_0 is the dissociation energy of N_2F_4 , here taken to be 77 kJ/mol (18.4 kcal/mol). For the other diluent gases, the activation energy was unchanged.

A mass spectrometer with a collision-free modulated molecular beam sampling system was used to obtain the mass spectrum of N_2F_4 and to study ionization and dissociation processes in N_2F_4 and NF_2 [477]. Surprisingly, dissociation of N_2F_4 into NF_2 radicals at 300 K at very low pressures, for which the degree of dissociation should be almost 100% at equilibrium, was found to be a slow process, an N_2F_4 molecule readily surviving the order of 10^6 wall collisions without decomposing. To obtain substantial conversion of N_2F_4 into NF_2 , it was necessary to send the sample through a heated line at the inlet of the mass spectrometer. Appearance potentials were determined for selected ions from N_2F_4 and NF_2 and the relevant processes identified. The bond dissociation energy $D(\text{F}_2\text{N}-\text{NF}_2) = 0.94 \pm 0.1 \text{ eV} = 90.4 \pm 13.4 \text{ kJ/mol} = 21.6 \pm 3.2 \text{ kcal/mol}$ was directly obtained from the appearance potentials of the NF_2 ion from NF_2 and N_2F_4 . Other thermochemical energies were measured as follows: $D(\text{NF}-\text{F}) = 3.15 \pm 0.10 \text{ eV} = 304 \pm 9.6 \text{ kJ/mol} = 72.8 \pm 2.3 \text{ kcal/mol}$, ionization potential (N_2F_4) = $12.00 \pm 0.1 \text{ eV}$, ionization potential (NF_2) = $11.76 \pm 0.1 \text{ eV}$, and ionization potential (NF) = $12.24 \pm 0.1 \text{ eV}$.

At higher temperatures, N_2F_4 decomposes to a mixture of NF_3 and N_2 :

The pyrolysis of N_2F_4 has been studied from 578 to 791 K [478–480]. The reaction rates were measured, and the effects of surface area to volume, inert diluent gas pressure, and nitric oxide (a radical scavenger) addition have been examined. The reaction rate was found to exhibit good second-order behavior at temperatures above 678 K. The general rate expression is

$$k_1 = 10^{9.0 \pm 0.4} \exp \left(-36950 \pm \frac{500}{RT} \right)$$

where k_1 is the rate constant in s^{-1} and T is the temperature in kelvin.

The shock-initiated thermal dissociation of $\text{N}_2\text{F}_4 \rightleftharpoons 2\text{NF}_2$ in excess argon and nitrogen has been investigated over the temperature range 351–453 K at total pressures 1.0–9.4 atm in Ar and 0.69–12.0 atm in N_2 [481]. The progress of the reaction behind incident shock waves was followed by monitoring the NF_2 radical concentration in absorption at 260 nm using a time-resolved spectrophotometric technique. Assuming that the activation energy in the high-pressure limit may be approximated by the enthalpy of reaction, the high-pressure limiting rate constant was given by

$$k_{Ar} = 10^{15.37} \exp(-19800/RT)$$

where k_{Ar} is the rate constant in argon in s^{-1} and T is the temperature in kelvin. A similar value was obtained from the N_2F_4 - N_2 data. At pressures below 2 atm, the rate was essentially in the second-order region, and the bimolecular rate constants for the N_2F_4 -Ar data were found to be in good agreement with literature values. The combined data may be represented by

$$k_{\text{bi}}^{\circ} = 10^{13.56 \pm 0.1} \exp\left(-15300 \pm \frac{600}{RT}\right)$$

where k_{bi}° is the bimolecular rate constant in $\text{mol}^{-1} \text{s}^{-1}$ and T is the temperature in kelvin.

3.4.2 Photolysis of Tetrafluorohydrazine

It was hoped that photolysis of NF_3 or N_2F_4 in the presence of an excess of fluorine would produce higher fluorides of nitrogen ($\text{NF}_5?$), but that has not yet been shown. The other reason that the photolysis of N_2F_4 was studied in detail is that N_2F_4 may be used as a source of fluorine atoms in chemical lasers with D_2 . A pulsed CO_2 laser was used to initiate and sustain the dissociation of N_2F_4 by depositing energy directly in the vibrational degrees of freedom [482]. The photolytic dissociation proceeded at an initial rate that far exceeded the measured thermal dissociation rate.

Stimulated laser emission was obtained as a result of vibration-rotational transitions in HF and DF molecules in $\text{N}_2\text{F}_4 + \text{H}_2$ and $\text{N}_2\text{F}_4 + \text{D}_2$ mixtures [483]. The stimulated emission was initiated by CO_2 laser pulses of $\lambda = 10.3 - 10.6 \mu\text{m}$ wavelength. The peak output power of the HF laser was 500 W and that of the DF laser was 1000 W for pulses of 1.2 and 0.5- μs duration, respectively.

Tetrafluorohydrazine induced passive Q-switching in a CW CO_2 laser in both the P and R branches of the 10.4- μm system, showing comparable effectiveness on all the accessible lines [484]. At higher pressures, this gas forced the laser to oscillate in the 9.3- μm system in non-frequency-selective cavities.

The photodissociation of N_2F_4 by a strong nanosecond-duration CO_2 laser pulse was studied by probing the interaction volume with both UV and IR beams [485]. Up to 20% of the molecules were found to be dissociated into NF_2 during the first few nanoseconds following the passage of the pulse.

The dissociation of N_2F_4 by CO_2 laser radiation and the N_2F_4 fluorescence were measured at very low pressures from 5 $\mu\text{m Hg}$ down to the collision-free region [486, 487]. The products of thermal heating and collision-free multi-photon absorption were distinguished via the time-resolved UV absorption of NF_2 following the laser pulse. The rate constant for dissociation of vibrationally excited N_2F_4 was $k = (1.0 \pm 0.4) \times 10^6 \text{ LMW}^{-1} \text{ cm}^{-3} \text{ s}^{-1}$ at a N_2F_4 partial pressure of 0.28 mbar and argon diluent partial pressure of 1 mbar.

An online diagnostic system was used to investigate the kinetics of the $\text{N}_2\text{F}_4 = 2\text{NF}_2$ dissociation in a high-power pulsed CO_2 laser field [488]. It was found

that at N_2F_4 pressures of 3–15 mmHg and incident energy densities of 0.2–3 J/cm², collisions did not have a significant influence on the excitation and dissociation process, and its rate was governed by the rate of radiative activation of the molecules. The intramolecular relaxation time of N_2F_4 was estimated from the experimental results. The experiment was interpreted satisfactorily, assuming that the behavior of N_2F_4 molecules in the field is characterized only by the dependence of the stimulated transition cross-section on the molecular energy $\sigma(E)$ and by the dissociation energy that corresponds to the breaking energy of the weakest N–N bond. At low excitation levels (~1 photon/molecule), the process was in thermodynamic equilibrium, and its kinetics was governed by the condition for adiabatic dissociation [489]. An increase in the energy input to ~3 photons/molecule gave rise to a radiative dissociation stage that was independent of pressure. This was followed by non-equilibrium collisional dissociation involving additional activation with a radiative molecular energy distribution function.

Saturation parameters and absorption characteristics of N_2F_4 at 10.6 μm were studied using an intense 1.5-ns excitation pulse and a low-CW CO_2 laser-probe beam [490]. It was found that, for short-pulse interaction, a four-level model could describe satisfactorily the experimental results at pressure up to 120 mmHg. The main parameters of the model were a rotational-rotational exchange constant of 47 ns $\times$ mmHg, a fundamental radiative cross-section of 1×10^{-16} cm², a contribution of 1/60 of the ground-state population to absorption, and a residual absorption coefficient equal to 20% of the small signal absorption at low pressure.

The photolysis of N_2F_4 in the presence of bromine gives N_2F_2 [491, 492].

3.4.3 Radiolysis of Tetrafluorohydrazine

Exposure of liquid N_2F_4 at 77 or 105 K to intense X-ray radiation from a 3-MeV X-ray source with dose rates up to 100 Mrad/h resulted in the formation of a mixture of N_2 , F_2 , NF_3 , *cis*- N_2F_2 , and *trans*- N_2F_2 [243, 244]. The evolution of decomposition products was analyzed by online mass spectrometry. The F_2 concentration peaked after 10 min and then dropped to zero. No higher fluorides of nitrogen (NF_5 ??) were found.

3.5 Handling of Tetrafluorohydrazine

The odor of N_2F_4 is very irritating and similar to that of elemental fluorine. Very little information is available on short-term and long-term toxicity of N_2F_4 .

When N_2F_4 was still commercially available, it was stored and shipped in steel cylinders conforming to ICC-3 AA-2265 regulations at 6.8 atm (100 psi). At the point of manufacture, larger quantities were stored as a cryogenic liquid in copper vessels holding up to 10 kg of N_2F_4 .

3.6 Compatibility with and Corrosion of Materials in Tetrafluorohydrazine

Organic materials of construction, for instance glass-fiber reinforced plastics, are not suitable for operation with N_2F_4 . The oil in vacuum pumps connected to N_2F_4 systems must only be of the perfluorinated kind.

3.7 Handling and Safety Properties of Tetrafluorohydrazine

In 1986, the U.S. Air Force showed a renewed interest in N_2F_4 and initiated a summary of known test results and handling safety. Because only limited testing had been conducted initially on N_2F_4 , further tests were considered necessary. To further characterize N_2F_4 hazards, tests determining flammability, spontaneous ignition, incompatibility, and explosion hazards, as well as the toxicity and environmental effects, were recommended. Flame ignition and propagation tests were recommended using standard techniques for measurement of flammability limits, ignition energies, the maximum experimental safety gap, and burning velocity to determine flammability hazards. Incompatibility hazards should be assessed by corrosion studies performed on materials exposed to liquid and vapor N_2F_4 , in addition to shock-sensitivity tests performed on non-metallic materials after exposure.

3.7.1 Toxicity of Tetrafluorohydrazine

Rats and dogs were exposed to several concentrations of N_2F_4 below the previously determined rat 15 and 60-min LC50s to determine the intermediate, non-lethal level effects [493]. No histopathologic changes were observed in animals exposed to lethal or sub-lethal concentrations of N_2F_4 in the 15 and 60-min exposures. However, some pathologic changes involving the lungs, spleens, and livers were observed in animals exposed to lethal concentrations in the 4-h exposures. The toxic signs were cyanosis, hematologic changes, and eye and nasal irritation. Rats showed signs of eye and nasal irritation at concentrations causing no such effects in dogs. However, at these concentrations dogs had a greater increase in methemoglobin in the blood than did the rats.

Early on in preparing for animal-exposure studies, it was recognized that N_2F_4 was so unstable in the atmosphere that there was some doubt whether exposed animals would ever come into contact with the unadulterated parent compound. Studies of N_2F_4 poisoning were therefore paralleled by, and became dependent upon, chemical studies that were begun in an effort to identify the terminal products to be expected of the reaction of N_2F_4 with moist air. Inhaled N_2F_4 at concentrations of 1% (10000 ppm) in air was lethal to rats after about 25 min of exposure [283]. Thirty-minute exposures to 1% N_2F_4 were found to be lethal before the end of exposure in every case. Exposures at this concentration for 25 min usually resulted in death before removal from the exposure chamber or within 10 min after removal. Twenty minutes

in this atmosphere was not lethal. Lethally affected animals occasionally died within the few minutes after emergence from the chamber, but if they survived this period, they rarely died. The tests indicated that the acute lethal effect of N_2F_4 inhalation may be due to methemoglobin formation. N_2F_4 caused a localization of fluoride in red blood cells that persisted at least 24 h, and in these respects was similar to the effect of NF_3 .

Exposure to 10000 ppm N_2F_4 for 25 min or longer was lethal to rats [494]. If N_2F_4 did not decompose prior to inhalation, lethal concentrations caused oxidation to methemoglobin of as much as 65% of total hemoglobin. Decomposed N_2F_4 was approximately as lethal, however, with only moderate formation of methemoglobin. The LD50 of the gas injected intraperitoneally was about 0.5 mmol/kg, with limited methemoglobinemia. The chemistry of N_2F_4 decomposition in air was reviewed in the context of toxic atmospheres expected after accidental release of the agent. As long as intact N_2F_4 remains in an atmosphere, the principal degradation products present will be NO and HF. With the disappearance of N_2F_4 , NO_2 will accumulate. N_2F_4 exposure is thus to a mixture of N_2F_4 and hydrolysis products.

3.7.2 Detonability of Tetrafluorohydrazine

Tetrafluorohydrazine or nitrogen trifluoride is not detonable under most conditions of initiation, in contrast to other nitrogen halides such as nitrogen trichloride or nitrogen triiodide. In a steel pipe with a diameter of 1 in and length of 8 in initiated with booster charges consisting of two tetryl pellets with diameter of $1 \times 1\text{-}5/8$ in, a charge of liquid N_2F_4 was not detonable [495]. The temperature range was -196 to 100°C .

In another test with 2.5-cm (1-in.) internal-diameter charges initiated by 100-g tetryl boosters, no propagation was observed [496]. In adiabatic compression U-tube tests, none of the samples exploded under the conditions tested.

3.8 Environmental Effects of Tetrafluorohydrazine

Several inorganic fluorides were reviewed for their chemical, physical, toxicologic, and environmental effects properties [300]. Seeds and seedlings of bean, corn, pea, squash, and Sudan grass were exposed to air or water mixtures of these compounds. Exposure of dry seeds to a gaseous 100% NF_3 atmosphere for 1–8 h caused inhibition of subsequent germination depending on the seed species. Exposure of seeds to a 10% N_2F_4 atmosphere for 1 h completely inhibited germination of all five species of seeds. Concentrations of N_2F_4 or NF_3 up to 10000 ppm in air were required to cause visible damage of plant seedlings after a 30–60-min exposure period.

3.9 Applications of Tetrafluorohydrazine

3.9.1 Laser Applications of Tetrafluorohydrazine

Similar to chemical lasers using difluorine or nitrogen trifluoride to generate fluorine atoms that can then react with hydrogen or deuterium in a lasing cavity, tetrafluorohydrazine or its dissociation product difluoroamino free radical is a good source for fluorine atoms as well [303].

A laser emission spectrum was investigated of excited DF molecules produced by chemical reaction in mixtures of $D_2 + F_2$, $D_2 + NF_3$, $D_2 + N_2F_4$, and $D_2 + NO_2F$ at a pressure of ~ 133 Pa (~ 1 mm Hg) [497]. The largest number of laser lines (including those in the 1-0 band) was observed in the $D_2 + NF_3$ laser. The increase and decay behavior of the intensity of different lines elucidated peculiarities ascribed to a temperature increase of the mixture during the reaction and to cascade transitions.

4 Difluorodiazene

Difluorodiazene, N_2F_2 , is of no use as a rocket propellant. We mention it here only because it is a frequently observed undesirable, explosive contaminant of other more desirable nitrogen fluorides. Its properties must be known to be able to identify it as a contaminant and to eliminate it from improved preparation methods for NF_3 and N_2F_4 , which have industrial uses and have been evaluated as rocket and laser propellants. Difluorodiazene has been found to be an active polymerization initiator for fluoropolymers such as tetrafluoroethylene. It is an intermediate in the synthesis of fluoronitrogen salts, which are more stable than the N_2F_2 they are made from.

Difluorodiazene, N_2F_2 , (also called dinitrogen difluoride, 1,2-difluorodiazene, 1,2-difluorodiimide, or difluorodiazene) is a colorless gas. It exists in two stereoisomers, a *cis*- and a *trans*-difluorodiazene. The CAS RN of *cis*-difluorodiazene is [13812-43-6], and the CAS RN of *trans*-difluorodiazene is [13776-62-0]. The existence of an unsymmetrical isomer, 1,1-difluorodiazene, has been proven to be very unlikely.

4.1 Preparation of Difluorodiazene

Difluorodiazene was first obtained during the thermal decomposition of azidofluoride N_3F . N_2F_2 is also obtained as an unwanted by-product during the production of NF_3 by electrolysis of a NH_4HF_2 melt [498, 499].

Products of the reaction of NF_3 with mercury in a glow discharge are tetrafluorohydrazine, difluorodiazene, mercury fluorides, and nitrogen [386]. The yield of a given product can be varied by changing the NF_3 pressure, discharge current density, and the temperature of the discharge tube. The NF_3 is separated from the tetrafluorohydrazine and difluorodiazene by fractional distillation from an 87-K (-186°C) trap

cooled with liquid argon to a 77-K (-196°C) trap. With parallel fractionating systems, the discharge tube can be operated almost continuously with a minimum of NF_3 . The reaction products are essentially free of contamination. Mass spectrometer analyses have shown them to contain 0.1% of nitrogen oxides or silicon tetrafluoride. Tetrafluorohydrazine and the two forms of difluorodiazene can be separated by gas adsorption chromatography using a 5-ft silica gel column at 233 K (-40°C).

Pyrolysis of NF_3 in an electric arc results in the formation of some difluorodiazene as the pyrolysis product, a very wasteful procedure [500]. Difluorodiazene can also be obtained if one allows elemental fluorine to react with sodium azide at 293–343 K (20 – 70°C) [96, 97, 501]. Reactions of N_2F_2 with SF_4 , SO_2 , NO , and SbF_5 have been described [502]. The reaction of N_2F_2 with SbF_5 forms a salt $[\text{N}_2\text{F}]^+[\text{SbF}_6]^-$. Difluorodiazene is an unwanted byproduct of the production of tetrafluorohydrazine by hydrolysis of *N,N*-difluorourea, mostly done at low temperatures and high concentrations of caustic [503]. Pure *trans*- N_2F_2 can be obtained by reaction of N_2F_4 with AlCl_3 [504].

The scaled-up preparation of both *trans*- and *cis*- N_2F_2 using the Hurst-Khayat method is described in detail in [505–507]. The apparatus used in the preparation of *trans*- N_2F_2 followed the design described by Hurst and Khayat. The reactor consisted of a glass U-trap (~ 250 mL volume) connected to a vacuum line by ball joints. In a typical run, 15–18 g of dry AlCl_3 was sublimed onto the walls of the reactor. The reactor was cooled to 193 K (-80°C) and evacuated. One arm of the glass reactor was connected to a storage bulb containing 30 mmol N_2F_4 . The bulb was cooled to 138 K (-135°C) in order to maintain a pressure of 15–20 mm Hg during the run. The other arm of the reactor led to a manometer, and a train of collecting traps opened to a vacuum pump. Between the reactor and set of collecting traps was a Teflon needle valve, with which the flow of N_2F_4 through the reactor could be controlled. To initiate the reaction, 15 mm Hg of N_2F_4 was introduced into the reactor with the needle valve closed and was kept in contact with the AlCl_3 for 20–30 min. After the reaction was initiated, the Teflon needle valve was opened partially to allow a slow leakage of gas out of the reactor. The condensable products, *trans*- N_2F_2 , NF_3 , Cl_2 , and any unreacted N_2F_4 , were collected at 77 K (-196°C). Separation of the *trans*- N_2F_2 was effected by fractionation through 138 K (-135°C) and 77 K (-196°C) baths. Two fractionations gave a sample collected in the 77 K (-196°C) trap, which showed no Cl_2 by mass spectral analysis. The 77 K (-196°C) fraction was then left open to a vacuum pump at 77 K (-196°C) to remove the bulk of the NF_3 . Final analysis by IR showed *trans*- N_2F_2 and less than 1% NF_3 . N_2F_4 was not observed. Yields of *trans*- N_2F_2 were of the order of 10–12 mmol, or 35–40%, based on the amount of N_2F_4 used. In order to prepare *cis*- N_2F_2 , approximately 10 mmol *trans*- N_2F_2 was distilled into a 500-mL CRES-316 stainless steel container (0.5 atm) and heated overnight at 348–353 K (75 – 80°C) according to the procedure described by Hurst and Khayat. The contents of the cylinder were then cooled to 77 K (-196°C), and the non-condensables were pumped off. IR analysis of the condensable portion showed *cis*- N_2F_2 (90%), *trans*- N_2F_2 (10%), and a trace of NF_3 . The total recovery yield of N_2F_2 was 80–90%.

Difluorodiazene can be prepared by reaction of difluoroamine with alkali metal fluorides [508, 509]:

The photolysis of N_2F_4 in the presence of bromine gives N_2F_2 [491, 492].

4.2 Physical Properties of Difluorodiazene

The boiling point of *cis*-difluorodiazene was estimated to be 167.5 K, a few degrees higher than that of *trans*-difluorodiazene. The boiling point of *trans*-difluorodiazene was found at 161.8 K, and the freezing point was at 101 K.

The isomers of N_2F_2 have been characterized in the past by their reactivity toward mercury. Investigation of the IR spectra showed that inactive N_2F_2 is *trans*-1,2-difluorodiazene and may be identified by the single strong band centered at 989 cm^{-1} [510]. The suggestion that active N_2F_2 resembles 1,1-difluorodiazene instead of a *cis*-isomer was later proven by other investigators to be in error.

In order to determine the molecular structure, the microwave spectra of the $\text{F}^{14}\text{N}^{14}\text{NF}$ and $\text{F}^{15}\text{N}^{14}\text{NF}$ isotopic forms of the “active” isomer of N_2F_2 were measured in the gas phase [511, 512]. From this information the structure could be derived as planar and *cis* with the following structural parameters: $d(\text{N}-\text{N}) = 1.214 \pm 0.005\text{ \AA}$, $d(\text{N}-\text{F}) = 1.384 \pm 0.01\text{ \AA}$, $\angle\text{FNN} = 114.5 \pm 0.5^\circ$. The dipole moment $0.16 \pm 0.01\text{ D}$ was derived from the rotational Stark effect. From relative intensity measurements of an excited vibrational, a vibrational frequency of $300 \pm 35\text{ cm}^{-1}$ was estimated.

The assignment of ^{19}F NMR spectra of the two isomers of N_2F_2 was consistent with the assumption of *trans* and *cis* 1,2-difluorodiazene structures for these molecules [513]. The qualitative features of the $^{19}\text{F} - \{^{14}\text{N}\}$ double-resonance spectra and a comparison of the ^{19}F NMR spectra at 56.4 and 40.0 MHz strongly favored a *cis* structure over a 1,1-difluorodiazene structure for the more reactive isomer. A comparison of the indirect N—F coupling constants for the two isomers indicated that the $\angle\text{FNN}$ angles are probably quite different for *cis* and *trans* N_2F_2 .

Initial assignments of fundamental vibrations in gaseous *trans*-difluorodiazene based on IR and Raman spectra were as follows: $\nu_{\text{NN}} = 1522\text{ cm}^{-1}$, $\nu_{\text{NF}} = 1010\text{ cm}^{-1}$, $s\delta_{\text{NF}} = 600\text{ cm}^{-1}$, $a\nu_{\text{NF}} = 990\text{ cm}^{-1}$, $a\delta_{\text{NF}} = 423\text{ cm}^{-1}$, and torsion = 363.5 cm^{-1} [514].

The Raman spectrum of *cis*- N_2F_2 has been measured, and the assignment of the in-plane fundamentals was established as follows: $\nu_1 = 1526\text{ cm}^{-1}$, $\nu_2 = 884\text{ cm}^{-1}$, $\nu = 341\text{ cm}^{-1}$, $\nu_6 = 945\text{ cm}^{-1}$, $\nu_{6'} = 729\text{ cm}^{-1}$ [515]. There was a weak feature in the Raman spectrum at $\sim 550\text{ cm}^{-1}$ that may be the torsional fundamental. The IR spectrum was then remeasured, and the 341 cm^{-1} vibration was located as a type-B band.

Two type-A bands of *trans*- N_2F_2 have been resolved and analyzed to yield estimates of the rotational constant $B_c = (B + C)$ of 0.14821 and 0.14876 cm^{-1} [516]. These values were consistent with the geometry previously obtained from electron diffrac-

tion measurements; i.e., $r_{\text{N-N}} = 1.224 \text{ \AA}$, $r_{\text{N-F}} = 1.397 \text{ \AA}$, $\angle \text{NNF} = 106.3^\circ$. Two type-B and two type-C bands have been partially resolved and aided in the description of the molecular structure.

The Raman spectrum of gaseous *trans*-N₂F₂ has been recorded and analyzed [517]. All three symmetric vibrations were obtained and assigned as follows: N—F symmetric stretch, 1018 cm^{-1} ; N—N stretch, 1523 cm^{-1} ; and N—N—F symmetric bend, 603 cm^{-1} . The IR and Raman spectra proved that the structure of *trans*-N₂F₂ belongs to point group *C*_{2h}. The Raman data also made possible a more complete assignment of the IR combination lines.

4.2.1 Molecular Structure of Difluorodiazene

Two planar isomers of N₂F₂ are known, the *cis* isomer (*C*_{2v}, melting point 78 K, boiling point 167.3 K, dipole moment 0.18 D) and *trans* isomer (*C*_{2h}, melting point 101 K, boiling point 161.8 K, dipole moment 0 D). The conversion of one form into the other can be achieved by warming, whereby the *trans* isomer is the more stable and less reactive form of the molecule. At 298 K the equilibrium has about 90% *cis* and 10% *trans*, and at about 342 K the *trans* isomer rearranges to the *cis* form. The unsymmetrical structural isomer F₂N=N could not be isolated and exists only on paper or as a short-lived transient during the decomposition of other fluorides.

The shortening of the N=N bond in the *cis* isomer, which is accompanied by a lengthening of the N—F bond, can be explained by negative hyperconjugation.

Synthesis of N₂F₂ by the electrolysis of ammonium bifluoride invariably leads to a mixture of the *cis* (85%) and *trans* (13%) isomers. Thermodynamically the *cis* form is favored over the *trans* form, the barrier being 134 kJ/mol (32 kcal/mol). Structure studies revealed that both molecules are planar, with an N—N distance of 1.25 Å and a *d* N—F of 1.44 Å in the *trans* form and *d* N—F of 1.384 Å in the *cis* form [518].

The decomposition of ¹⁵N₃F at 253 K (−20 °C) leads to a mixture of *cis*- and *trans*-¹⁵N₂F₂. The corresponding ¹⁹F NMR spectra were analyzed as [AX]₂ systems. ¹⁹F, ¹⁵N, and ¹⁴N NMR spectra were simulated using the DSYMPCD, DCYMPCD, and WIN-DAISY programs running under WIN-NMR [519]. Stereospecific coupling constants were obtained for both isomers. Comparison of the ¹⁹F NMR spectra from both ¹⁵N₂F₂ and ¹⁴N₂F₂ overcomes the inherent ambiguities of the analysis.

Isopropyl-*N,N*-difluorocarbamate is a stable liquid. Reaction of isopropyl-*N,N*-difluorocarbamate with potassium *tert*-butoxide gives a quantitative yield of difluorodiazene in a mix of 3 : 1 of *trans*:*cis* stereoisomers [520]. When isopropyl-*N,N*-difluorocarbamate is added to a chilled solution of aniline in methylene chloride, difluoroamine is obtained instead. Difluoroamine has been known to explode violently and must be handled using precautions. See also [521–525].

A semiempirical molecular orbital (MO) method (CNDO/2) with empirical constants adjusted to give agreement with ground-state geometries has been used to study

isomerization mechanism in the N_2F_2 system [526]. Calculated transition states did not correspond to the simple postulated transition states.

The isomerization of *trans*- N_2F_2 to *cis*- N_2F_2 going through $[\text{N}_2\text{F}^+][\text{AsF}_6^-]$ was unpredictable, erratic, required two steps, and consumed an equimolar amount of AsF_5 . It was found that catalytic amounts of SbF_5 at 303 K (30 °C) can achieve this isomerization, but they still result in substantial N_2F_2 losses due to $[\text{N}_2\text{F}^+][\text{SbF}_6^-]$ formation [527]. When the reaction was carried out at 333 K (60 °C), surprisingly, $[\text{NF}_4^+][\text{SbF}_6^-] \cdot n\text{SbF}_5$ was formed. AlF_3 was also studied as a catalyst for the N_2F_2 isomerization and was found to be an ideal catalyst, resulting in very high conversions of *trans*- N_2F_2 and high yields of *cis*- N_2F_2 . AlF_3 can be used repeatedly without loss of activity or N_2F^+ salt formation.

4.2.2 Thermodynamic Properties of Difluorodiazene

The thermodynamic properties of the two difluorodiazenes are summarized in Table 18.

Table 18: Thermodynamic properties of difluorodiazenes.

Property	Units	<i>cis</i> -difluorodiazene	<i>trans</i> -difluorodiazene
$\Delta_f H^\circ_{\text{gas}}$	kJ/mol	+68.62	+81.17
$S^\circ_{\text{gas, 1 bar}}$	J mol ⁻¹ K ⁻¹	259.80	262.63

Data source: [132]

Once the IR absorption bands of a molecule are known, the vibrational frequencies and moments of inertia can be calculated, and from there the thermodynamic functions can be derived [528].

The heats of reaction associated with the reaction

were observed for two mixtures containing the *trans* and the “active” isomeric forms of difluorodiazene in different proportions [529]. From the observed heats of reaction of the two samples, the heat of isomerization ΔH_{298} of “active” to *trans*- N_2F_2 was found to be 12.5 kJ/mol (3.0 kcal/mol). With the use of known auxiliary data for NH_3 and NH_4F , the heats of formation $\Delta H_f^\circ_{298}$ were determined to be +81.1 and +68.6 kJ/mol (+19.4 and +16.4 kcal/mol) for the gaseous *trans* and the “active” isomers, respectively. A similar method had previously been used by the same authors to determine the enthalpy of formation of nitrogen trifluoride.

The energy barrier to isomerization is $k = 10^{14} \exp(-32.2 \text{ kcal}/RT) \text{ s}^{-1}$ [530]. In this study, *trans*-difluorodiazene, highly diluted in argon (1:70), was heated in a single-

pulse shock tube. The reaction mixture was heated by reflected shock waves to elevated temperatures, where it reacted for a short period of time.

A calorimetric method was used to determine the enthalpies of formation ΔH°_{f298} of several nitrogen fluorides, based on their reaction with aqueous KI solutions in a calorimeter [139]. The values of ΔH°_{f298} recommended for *cis*-N₂F₂ (assumed to be identical for *trans*-N₂F₂) were listed. From the ΔH°_{f298} and ΔS°_{f298} values, the thermodynamic bond energies for the nitrogen fluorides were calculated.

4.3 Thermal Stability of Difluorodiazene

Difluorodiazene is unstable at room temperature and will decompose to nitrogen and nitrogen trifluoride. Difluorodiazene can be stored only at temperatures below 203 K (−70 °C). If it is heated rapidly to above 473 K (200 °C), decomposition may proceed with explosive speed. At 570 K, N₂F₂ dissociates to the elements.

4.4 Reactions of Difluorodiazene

Many investigators have commented on the differences in reactivity between *cis*- and *trans*-difluorodiazene. The two isomers react very differently. The *cis* form is more stable as well as more reactive. The *trans* form can be stored in glass vessels, whereas the *cis* form reacts slowly with glass to form SiF₄ and N₂O. However, *trans*-difluorodiazene is only slightly more resistant to chemical attack by water and aqueous acids than is *cis* isomer. Both are unaffected by water at 333 K (60 °C) for a period of 15 h [203, 504]. The *cis* isomer reacts slowly at 347 K (74 °C) (30% decomposed in 17 h), while the *trans* isomer reacts at a similar rate at 362 K (89 °C). In both cases, the hydrolysis products are nitrogen, oxygen, and hydrogen fluoride. The strong nucleophile OH[−] does not significantly accelerate the reaction, and very little N₂O is formed. This indicates that the hydrolysis does not proceed by nucleophilic attack on N₂F₂.

4.4.1 Salts of Difluorodiazene

The reaction of N₂F₂ with strong Lewis acids forms fluorodiazonium (fluorodiazonium) N₂F⁺ salts. The existence of solid adducts of N₂F₂ and Lewis acids, such as AsF₅ and SbF₅, is well known. In all cases an IR band at about 1060 cm^{−1} was observed that was attributed to the N—F stretching vibration of the N₂F⁺ cation. N₂F⁺ salts are important precursors in the synthesis of N₅⁺ compounds, and better production methods are needed for their larger-scale production. For the preparation of N₅⁺ salts on a larger scale, it was necessary to prepare the corresponding precursors in an efficient manner and in larger quantities [531].

cis-Difluorodiazine and arsenium pentafluoride react at or below room temperature to form a solid fluorodiazonium hexafluoroarsenate $[\text{N}_2\text{F}^+][\text{AsF}_6^-]$ that is stable up to 323 K (150 °C) and is soluble in anhydrous H_2F_2 [532, 533].

The existence of trifluorodiazyl ions in BrF_5 and in IF_5 was established by ^{19}F NMR and IR analyses. Solutions of $\text{N}_2\text{F}_3\text{AsF}_6$ in IF_5 treated with perchlorates showed absorptions of N_2F_3^+ and ClO_4^- in the IR [534]. Attempts to isolate trifluorodiazyl perchlorate from solution were not successful. An attempt to prepare N_3F_5 by reaction of $\text{N}_2\text{F}_3\text{AsF}_6$ with triphenyl fluoroaminomethane at 203 K (−70 °C) resulted in the formation of N_2F_4 and *trans*- N_2F_2 . Attempts to prepare new interhalogen oxides by the fluorination of $\text{Cl}_2\text{O}_2\text{AsF}_6$ and $\text{NOClO}_2\text{AsF}_6$ were unsuccessful.

The IR and Raman spectra for $[\text{N}_2\text{F}]^+[\text{AsF}_6]^-$ and $\text{N}_2\text{F}_2 \cdot 1.3\text{SbF}_5$ were reexamined, and previous assignments of the two stretching modes for N_2F^+ were confirmed, but the deformational mode was shown to occur at 390 cm^{-1} and not at 803 cm^{-1} [535]. Force constants were then calculated for N_2F^+ and compared to those of a series of isoelectronic molecules and ions.

A new, marginally stable N_2F^+ salt, $\text{N}_2\text{F}^+\text{Sn}_2\text{F}_9^-$, was prepared and characterized [536, 536]. A crystal structure was obtained for $\text{N}_2\text{F}^+\text{Sn}_2\text{F}_9^-$, resulting in the first observation of individual $\text{N}\equiv\text{N}$ and $\text{N}-\text{F}$ bond distances for N_2F^+ in the solid phase. The observed $\text{N}\equiv\text{N}$ and $\text{N}-\text{F}$ bond distances of 1.089 and 1.257 Å, respectively, are among the shortest experimentally observed $\text{N}-\text{N}$ and $\text{N}-\text{F}$ bonds. High-level electronic structure calculations showed that *cis*- N_2F_2 is more stable than *trans*- N_2F_2 by 1.4 kcal/mol at 298 K. The calculations also demonstrated that the lowest uncatalyzed pathway for the *trans-cis* isomerization of N_2F_2 has a barrier of 251 kJ/mol (60 kcal/mol) and involves rotation about the $\text{N}=\text{N}$ double bond. This barrier is substantially higher than the energy required for the dissociation of N_2F_2 to N_2 and 2F. Therefore, some of the N_2F_2 dissociates before undergoing an uncatalyzed isomerization, with some of the dissociation products probably catalyzing the isomerization. Furthermore, it was shown that the *trans-cis* isomerization of N_2F_2 is catalyzed by strong Lewis acids, involves a planar transition state of symmetry C_s , and yields a 9:1 equilibrium mixture of *cis*- N_2F_2 and *trans*- N_2F_2 . The increased reactivity of *cis*- N_2F_2 with Lewis acids and the exclusive formation of *cis*- N_2F_2 in the reaction of N_2F^+ with F^- can be explained through its electronic structure. Only *cis*- N_2F_2 and not *trans*- N_2F_2 forms N_2F^+ salts with Lewis acids. The geometry and vibrational frequencies of the $\text{F}_2\text{N}=\text{N}$ isomer have also been calculated and imply strong contributions from ionic $\text{N}_2\text{F}^+ \text{F}^-$ resonance structures, similar to those in F_3NO and FNO .

Solutions of N_2F_2 in SbF_5 are initially blue but fade rapidly to yellow. Electron magnetic resonance was used to determine whether the blue color originates from free radicals [537].

Raman spectra supplement the information that can be obtained from IR spectra. In particular, the existence of an N_2F^+ ion in the solid adduct obtained from N_2F_2 and AsF_5 could be proven by this method [538].

The $\text{N}_2\text{F}^+\text{AsF}_6^-$ salt was prepared from *trans*- N_2F_2 by thermal *trans-cis* isomerization in the presence of AsF_5 at 343 K (70 °C) [539]. The crystal structure of $\text{N}_2\text{F}^+\text{AsF}_6^-$ is monoclinic, space group $C2/m$ with $a = 9.184(5) \text{ \AA}$, $b = 5.882(2) \text{ \AA}$, $c = 5.160(2) \text{ \AA}$, $\beta = 90.47(4)^\circ$, $Z = 2$. The resulting N—F bond length of $1.217 \text{ \AA}$ is by far the shortest presently known N—F bond, while the N—N bond length of $1.099 \text{ \AA}$ is comparable to the shortest presently known $\text{N}\equiv\text{N}$ bond length of $1.0976 \text{ \AA}$ in N_2 . The surprising shortness of both bonds is attributed to the high s-character (sp hybrid) of the σ -bond orbitals on nitrogen and the formal positive charge on the cation. Upon going from sp^3 hybridized NF_4^+ ($1.30 \text{ \AA}$) to sp hybridized N_2F^+ , the N—F bond is shortened.

5 Other Nitrogen Fluorides

5.1 Nitrogen Pentafluoride

In the hope of replicating the synthesis of chlorine pentafluoride from the trifluoride and elemental fluorine under extreme conditions, 1:1 mixtures of nitrogen trifluoride and difluorine at very high pressures (8.1–9.5 MPa [80–94 atm]) were irradiated with fission fragments and neutrons created by fission of fully enriched $^{235}\text{UF}_6$ within the sample capsules [540]. Gas chromatography showed a new compound that was not identical to either *cis*- or *trans*- N_2F_2 or N_2F_4 and eluted at a retention time indicating a boiling point of 223 K (−50 °C). Mass spectrometry showed a peak at $m/e = 90$ that could be NF_4^+ or a fragment of the unknown F_3NNF_3 . This observation has not been repeated or confirmed by other investigators. If NF_5 existed, it would make a good rocket propellant oxidizer.

The structure, bonding, harmonic vibrational frequencies, and decomposition reactions of NF_5 were studied employing five different computational methods with single, double (CCSD), and perturbative triple excitations in conjunction with different basis sets. [541] The overall $\text{NF}_5 \rightarrow \text{NF}_3 + \text{F}_2$ reaction is exothermic with 176 kJ/mol (42 kcal/mol). The trigonal-bipyramidal form of $\text{NF}_5(D_{3h})$ was found to be a minimum at all levels of theory. A natural bond orbital comparison of NF_5 and PF_5 revealed the much greater polarity of the P—F than the N—F bonds. The weak ionic character and the relatively short $\text{F}\cdots\text{F}$ separations, within the sum of the van der Waals radii, are responsible for the metastable nature of NF_5 .

If NF_5 existed, it would be a violation of the octet rule that has governed chemical bond and molecular orbital theory for a long time, stating that the outer valence shell of second-row elements of the periodic table of elements (Li to Ne) cannot hold more than eight electrons [542].

5.1.1 Nitrogen Fluoride Anions

Nitrogen fluoride anions would be useful building blocks in the synthesis of catenated polynitrogen fluorides. It has been attempted to synthesize the dinitrogen fluoride anion N_2F^- or the trinitrogen difluoride anion N_3F_2^- by reaction of $(\text{CH}_3)_4\text{N}^+\text{F}^-$ with N_2F_2 , N_2F_4 , FNO , or FNO_2 , but no anions could be found [543]. One potential, still unknown nitrogen fluoride anion would be

which is analogous to the nitrite anion. A precursor for the synthesis of N_3F_2^- compounds is fluorine azide; this compound is extremely shock sensitive but can be safely used in solution.

5.2 Fluorine Azide

Fluorine azide, also known as azido fluoride, triazadienyl fluoride, N_3F , CAS RN [14986-60-8] is a very dangerous chemical. The very high heat of formation (about +544 kJ/mol [+130 kcal/mol]) of fluorine azide ($\text{N}\equiv\text{N}=\text{NF}$) makes it a candidate as an energetic material. It may be too sensitive to be used as a rocket propellant, but it can be used as a source of fluorine, fluoronitrene, and $\cdot\text{NF}$ free radicals in the study of fluorine laser reactions. It was speculated that it might be a precursor for the synthesis of the so-far unknown NF_5 or N_5F .

Fluorine azide was first prepared by reaction of hydrogen azide and difluorine [544, 545]. Good yields of FN_3 were obtained by reaction of 2 mol dry HN_3 with 1 mol F_2 gas at room temperature. The HN_3 was carried into the reaction chamber in a stream of dry N_2 at 45 cm³/min. Fluorine azide was characterized by its visible spectrum in GN_2 . In addition to a strong band at 410 mμ, weaker bands were observed at 378, 390, 397, 428, 439, and 444 nm. It was described as a greenish-yellow gas at room temperature, liquefying at 191 K (−82 °C) when diluted with nitrogen, and freezing to a yellow solid at 130 K (−143 °C). Evaporation of this solid generally resulted in a violent explosion. One drop of N_3F will pulverize any glass within a 5-cm distance. However, gaseous fluorine azide decomposed slowly at room temperature and very rapidly at 373 K (100 °C) without explosion, forming difluorodiazene (N_2F_2) and nitrogen. The thermal decomposition of gaseous N_3F into a mixture of *cis*- and *trans*- N_2F_2 and nitrogen at different temperatures was investigated quantitatively by IR spectroscopy [545]. At a pressure of 10–20 mbar and a temperature of 193 K (−80 °C), N_3F can be stored for several months without noticeable decomposition. The melting point of N_3F is 134 K (−139 °C) [546]. The vapor pressure can be expressed by the equation

$$\ln p = -(2.683 \times 10^3)/T + 17.958$$

where p is the vapor pressure in mbar and T is the temperature in kelvin. The extrapolated boiling point is 243 K (-30°C).

Microwave and IR spectra of FN_3 and its various ^{15}N -enriched isotopomers were recorded and analyzed, yielding data on molecular structure, dipole moment, and harmonic force constants [547]. The electronic and molecular structures of FN_3 and FONO_2 were calculated by using split-valence and d-orbital polarized basis sets and the GAUSSIAN 82 program [548].

Quantum chemical computations were used to describe the N_3F molecule and identify the energy levels and bond strengths [549]. The objective was to improve orbital optimization methods for different types of wave functions that could lead to substantial savings of computer time and memory and to predict new high-energy isomers for singlet and triplet states of N_3F and their kinetic stability with respect to isomerization and dissociation reactions. Additional studies also included the possibility of three-ring structured N_3F , a fluorotriazirine-type isomer [550]. The potential energy surfaces for the N_3F molecule have been studied using multi-configurational wave functions. Two new isomers were found, one on the singlet ($1\text{A}'$) and one on the triplet ($3\text{A}''$) surface. Both isomers have a three-numbered cyclic structure and C_s symmetry.

The low thermal stability of N_3F is apparent from its electronic structure determined by photoelectron spectroscopy [551].

Triazadienyl fluoride forms stable adducts with BF_3 and AsF_5 at low temperatures, as demonstrated by IR measurements [552]. The Lewis acids are bonded to the $\text{N}\alpha$ -atom of N_3F , as deduced from the data for ^{15}N -isotopically enriched N_3F . The basicity of N_3F is comparable to that of ethyne and ethene, according to the HF stretching frequency of the $\text{N}_3\text{F}/\text{HF}$ complex isolated in an argon matrix.

The burn rate of 5–80- μm -thick cryogenic films of fluorine azide was determined by schlieren photography to be $1.6 \pm 0.2 \text{ mm}/\mu\text{s}$ [553]. This rate was found to be strongly influenced by the presence of N_2F_2 , but less so by the presence of CO_2 . By analogy with the results from the gas-phase decomposition of fluorine azide, the nascent decomposition products were expected to be NF^* and N_2 . A thermal combustion mechanism driven by the energy released upon production and quenching of the excited NF^* species was proposed.

5.3 Other Nitrogen Fluorides

The possible existence of FN_5 was studied by *ab initio* electronic structure theory [554]. Calculations were carried out at various levels of theory for the $[\text{N}_5^+][\text{AsF}_6^-]$ ion pair and its decomposition to FN_5 and AsF_5 . Six possible vibrationally stable isomers of FN_5 have been identified. One of the possible structures is that of a linear 1-azido-2-fluorodiazene, CAS RN [610789-59-8]. These theoretical predictions were confirmed by an

experimental study of the thermolysis of N_5AsF_6 and $[N_5]_2SnF_6$ and the displacement of FN_5 from $[N_5]_2SnF_6$ with CsF using FTIR spectroscopy.

By way of definition, we call “binary fluorides” those that contain only one type of atom that is different from fluorine. Examples are ClF_3 and NF_3 . We call “ternary fluorides” those compounds that contain two different atoms other than fluorine. Examples are ClO_3F and NO_2F .

6 Nitrogen Oxygen Fluorides

Oxyfluorides of nitrogen, i.e., compounds containing the grouping $F-N-O$, have been known for many years in the form of simple compounds, such as nitrosyl fluoride ONF and nitryl fluoride O_2NF . Detailed studies of physical, structural, and chemical aspects of this class of compounds were conducted only after the potential of NF compounds as rocket propellants had been recognized. Several novel types of oxyfluorides of nitrogen, such as trifluoroamine oxide, F_3NO , have since been added to the list. The nitryl hypofluorite compound O_2NOF is also a potential rocket oxidizer [555, 556].

A summary of literature references on all nitrogen–oxygen–fluorine and chlorine–oxygen–fluorine compounds contains information on physicochemical properties (including spectral, structural, and thermodynamic properties) for NO_3F , FNO_2 , $ONOF$, FNO , F_2NNO , F_3NO , ClO_4F , ClO_3F , ClO_2F , $ClOF$, $ClF \cdot O_2F_2$, ClO_2F_3 , $ClOF_3$, and $ClOF_5$, along with reactivities with inorganic Lewis acids and bases [557]. It contains 159 references. Similar summaries are in [558].

6.1 Nitrosyl Fluoride

Nitrosyl fluoride (nitrosonium fluoride, NOF) is a colorless gas. It was first obtained by the addition of elemental fluorine to nitric oxide in a copper tube [559, 560]. It can also be obtained by reaction of $NOBF_4$ with NaF . The undiluted combination of nitric oxide and fluorine is a luminous flame reaction. The reaction proceeds with the emission of visible light [561]. Under different conditions, it may even produce some trifluoroamine oxide F_3NO .

Nitrosyl fluoride is not particularly suitable as a rocket propellant, and nobody has even patented it. It is interesting from a more academic point of view because of its close relationship with the more energetic nitryl fluoride and because it can form stable nitrosonium salts with Lewis acids that can be used to synthesize other energetic salts. NOF reacts with $NaOH$ to give NO , NaF , $NaNO_2$, and $NaNO_3$.

In a study of laser-induced reactions of tetrafluorohydrazine or nitrogen trifluoride with nitric oxide, nitrous oxide, nitrogen dioxide, or nitrosyl chloride, it was noted that absorption in the nitrogen fluorides of IR radiation from a CW carbon dioxide laser

initiated a number of reactions [562]. In all cases, the major product was FNO, and when nitrous oxide or nitrogen dioxide were used, FNO₂ was also produced.

The physical properties of nitrosyl fluoride are summarized in Table 19.

Table 19: Physical properties of nitrosyl fluoride.

Property	SI units	MKS units	References
Melting point	140.6 K	−132.5 °C	[559]
Boiling point	213.2 K	−59.9 °C	[559]
Density, liquid		$d = 1.919 - 0.002787 \text{ g/cm}^3$	[559]
Enthalpy of formation at 298 K, gas	−66.1 kJ/mol	−15.8 kcal/mol	[563]

6.2 Nitryl Fluoride

Nitryl fluoride, also known as NO₂F, “nitronium fluoride,” nitrogen dioxygen fluoride, CAS RN [10022-50-1] is a colorless gas that was obtained by the discoverer of elemental fluorine, Moissan, in one of the first reactions performed with the newly isolated element.

6.2.1 Preparation of Nitryl Fluoride

Nitryl fluoride can be obtained by direct combination of NO₂ and F₂ in a copper vessel. The reaction is not very exothermic [559]:

The vapor–liquid fluorination of NO or NO₂ in a fluorothene vessel proceeded very smoothly to yield 90% nitrosyl fluoride, NOF, or 90% nitryl fluoride, NO₂F, respectively [564].

Passing a stream of NO₂Cl over AgF in a platinum tube at 513 K (240 °C) formed NO₂F in a yield of 5% [565, 566]. Equivalent quantities of dry HF and BF₃ introduced into a solution of N₂O₅ in nitromethane formed crystals of NO₂BF₄, which when heated with NaF at 513 K (240 °C) in a platinum tube formed NO₂F. If SiF₄ was substituted for BF₃, the intermediate was (NO₂)₂SiF₆, but it could also be used to make NO₂F. For example, about 70 mL MeNO₂ was added to 3 g N₂O₅ cooled to 223 K (−50 °C), and the substance was allowed to dissolve at 233 K (−40 °C). After the addition of 0.6 g HF and BF₃, a crystalline precipitate of [NO₂⁺][BF₄[−]] was formed. After removal of the excess reaction product and the solvent by distillation *in vacuo*, the dry substance was mixed with NaF in a platinum crucible and heated to 473 K (200 °C) *in vacuo*. NO₂F evolved and was condensed in a liquid-air-cooled cold trap.

The rate of reaction between NO_2 and F_2 to form NO_2F was measured at 300.8, 323.5, and 343.3 K (27.7, 50.4, and 70.2 °C) [567]. Light absorption by NO_2 was used to follow the reaction. The rate was found to be first order in each reactant, and it showed no dependence on the NO_2F present. The empirical second-order rate constant k_1 is that of an elementary bimolecular reaction with $A = 1.6 \times 10^{12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ and $E = 44.0 \text{ kJ} = 10.5 \text{ kcal}$. It has been attempted to improve the yield of this method by modification of the conditions of reaction [568–571].

The reaction of OF_2 with NO_2 leads to a mixture of NO_2F , NO_3F , and O_2 , and the proportions of products depend on the operating pressure. At low pressure, this is a useful method for preparation of NO_2F . The thermal reaction between F_2O and NO_2 was studied at 333–353 K (60–80 °C) [572]. The reaction took place with a pressure decrease, 1 mol F_2O being used up for each 2 mol NO_2 . The reaction products varied with the total operating pressure and consisted of NO_2F , NO_3F , and O_2 . At very low pressure, only NO_2F and O_2 were formed in the mol ratio 4 : 1.

Nitryl fluoride can be prepared by first treating PF_5 with fuming HNO_3 , crystallizing the nitronium hexafluorophosphate, mixing nitronium hexafluorophosphate with pre-dried NaF in a platinum tube connected to three traps in series at 263, 193, and 83 K (–10, –80, and –190 °C), and heating the contents of the tube for 3 h at 473 K (200 °C) under a current of dry nitrogen [573]. Nitryl fluoride is a colorless gas, with boiling point 200.7 K (–72.4 °C) and melting point 107 K (–166 °C), and can be used as an oxidizer in rocket propellants.

Nitryl fluoride NO_2F can be prepared by passing N_2O_4 over a stirred bed of CoF_3 at 573 K (300 °C) [574]. The condensate from the gaseous product must then be distilled from the mixture and usually gives a yield of 89%. The CoF_2 formed can be regenerated by treatment with F_2 to re-form CoF_3 . An attempt to prepare NOF by passing NO over heated CoF_3 failed because of complex formation.

Nitryl fluoride can be prepared by heating an excess of a metal fluoride with NO_2 in a reactor [575]. For example CoF_3 was placed in a reactor and heated to ~573 K (~300 °C) with stirring and passing NO_2 gas over the continuously heated bed for ~30 min. The CoF_2 remaining was later regenerated by treating it with F_2 at 523–573 K (250–300 °C), thereby quantitatively reconvertng the CoF_3 . Similarly, CeF_4 , MnF_3 , or AgF_2 were reacted with NO_2 to produce FNO_2 .

Simple nitronium salts, e.g., nitronium hexafluoroarsenate or nitronium tetrafluoroborate, were formed by adding nitrogen dioxide, a metal fluoride, and fluorine gas to a vessel held at a low temperature and allowing the vessel to warm until a reaction occurred [576]:

Small quantities of nitryl fluoride can be prepared in the laboratory by a metathetical reaction of nitryl tetrafluoroborate and sodium fluoride [93]:

It has also been attempted to circumvent the need for elemental difluorine in the preparation of nitryl fluoride and nitrosyl fluoride by electrofluorination of N_2O , NO , NO_2 , or HNO_2 between electrodes in anhydrous hydrogen fluoride [577–579]. The presence of traces of water in the electrolyte, either introduced initially as contaminants in the reactants or formed as by-product during the reaction, leads invariably to the same reaction products, namely a mixture of OF_2 , NO_2F , and NO_3F , and the yields are very poor. The H_2F_2 can be dried by electrolyzing it for a while before introducing any nitrogen oxide [580, 581].

Nitryl fluoride can be made by fluorination of alkali metal nitrates with COF_2 . The interaction of LiNO_3 or NaNO_3 with COF_2 at 358 K (85 °C) in a stainless steel reactor in the presence of 12 mol-% CsF , an HF scavenger, resulted in nearly quantitative yields of NO_2F . No reaction was observed between CsNO_3 and COF_2 either in the presence or the absence of CsF .

6.2.2 Physical Properties of Nitryl Fluoride

Physical properties of nitryl fluoride are summarized in Table 20.

Table 20: Physical properties of nitryl fluoride.

	SI units	MKS units	References
Molecular mass	65.008 g/mol		
Melting point	107 ± 0.5 K	-166 ± 0.5 °C	[559]
	107 K	-166 °C	[573]
Boiling point	200.7 ± 0.2 K	-72.4 ± 0.2 °C	[559]
	200.7 K	-72.4 °C	[573]
Density, liquid at 200 K (-73 °C)	1494 kg/m ³	1.494 g/cm ³	[558]
Density, liquid at 172 K (-101 °C)	1571 kg/m ³	1.571 g/cm ³	[582]
Viscosity, liquid at 200.6 K (-72.5 °C)		4.60 mPs	[583]
Viscosity, liquid at 172 K (-101 °C)		5.72 mPs	[583]
Surface tension at 168.6 K (-104.5 °C)		27.6 dyn/cm	[582]
Critical temperature	349.5 K	76.3 °C	[582]
Standard enthalpy of formation, gas (ΔH) ₂₉₈	+108.78 kJ/mol	+26.0 kcal/mol	[583]
Heat of hydrolysis in water	-129.7 kJ/mol	-31 kcal/mol	[583]

6.2.2.1 Density of Nitryl Fluoride

The temperature dependence of the density of liquid nitryl fluoride can be expressed by the following equation [582, 584].

$$\rho = 2.046 - 0.00276T$$

where ρ is the density in g/cm^3 and T is the temperature in kelvin.

6.2.2.2 Vapor Pressure of Nitryl Fluoride

The vapor pressure of nitryl fluoride can be calculated from the following equation from Ruff, Menzel, and Neumann [559]:

$$\log p_v = -(5692/4.573T) + 1.75 \log T - (0.051606T/4.573) + 7.3187$$

where p_v is the vapor pressure in mm Hg and T is the temperature in kelvin.

6.2.2.3 Optical Properties of Nitryl Fluoride

Infrared Absorption Spectra of Nitryl Fluoride

The IR spectrum of nitryl fluoride was studied between 400 and 5000 cm^{-1} , and the Raman spectrum of the liquid at 168 K (-95°C) and the polarization of the lines were determined [585]. Frequency assignments were made in terms of an assumed planar C_{2v} structure, and the following assignments of fundamentals were proposed: $\nu_1(A_1) = 1312\text{ cm}^{-1}$; $\nu_2(A_1) = 822\text{ cm}^{-1}$; $\nu_3(A_1) = 460\text{ cm}^{-1}$; $\nu_4(B_1) = 1793\text{ cm}^{-1}$; $\nu_5(B_1) = 570\text{ cm}^{-1}$; $\nu_6(B_2) = 742\text{ cm}^{-1}$. Initially, the model C_{2v} was for an asymmetrical top, approximating for NO_2F to an oblate symmetrical top.

High-resolution IR spectra of FNO_2 were measured in the region of $1750\text{--}1825\text{ cm}^{-1}$ to obtain rotationally resolved IR line positions for the identification of FNO_2 as an atmospheric pollutant [586]. The spectrum in this range displayed extensive rotational structure consisting solely of b-type transitions that were assigned to ν_4 , the NO_2 anti-symmetric stretching vibration. Over 1500 IR and 51 microwave transitions were fitted to generate rotational constants for the $\nu_4 = 1$ state and improved constants for the ground state.

Another set of high-resolution IR spectra of FNO_2 of the strong a-type absorptions corresponding to the ν_1 ($n_0 = 1310.75\text{ cm}^{-1}$) and ν_2 ($n_0 = 821.9387\text{ cm}^{-1}$) bands were analyzed, and the n_1 line positions exhibited extensive perturbations as a result of three nearly degenerate vibrational states ($\nu_1, \nu_3 + \nu_6$ and $\nu_5 + \nu_6$) that interact through strong Coriolis coupling [587]. Line positions, assignments, and relative intensities for the dominant transitions in both bands were established, although a comprehensive analysis of the perturbations requires a detailed understanding of the lower-frequency vibrational states.

The gas-phase IR spectra of the ν_5 , ν_3 , ν_6 , and ν_2 bands of FNO_2 were studied at resolutions ranging from 0.0023 to 0.0050 cm^{-1} [588]. These bands form an isolated tetrad that is coupled by a-, b-, and c-Coriolis resonances. The c-Coriolis interaction

between ν_3 and ν_5 is particularly strong. From a ground-state combination difference analysis, the ground-state rotational constants were then obtained.

In a continuation of this effort, the ν_4 , $2\nu_6$, $\nu_2 + \nu_3$, and ν_1 bands of the gas-phase mid-IR region of the FNO_2 spectrum at $1200\text{--}1900\text{ cm}^{-1}$ were measured again at a resolution of 0.003 cm^{-1} [589]. Improved ground-state rotational and centrifugal distortion constants were obtained from a simultaneous analysis of earlier data and the present data from ν_4 and ν_1 . The ν_4 and $2\nu_6$ bands were free from local perturbations, and upper-state spectroscopic constants were obtained from the conventional Watson Hamiltonian. The bands ν_1 and $\nu_2 + \nu_3$ were strongly perturbed by Coriolis interactions with the nearby dark levels $\nu_5 + \nu_6$, $\nu_3 + \nu_6$ and $\nu_2 + \nu_5$. Upper state constants for ν_1 and $\nu_2 + \nu_3$ were obtained from triad and tetrad models, respectively, including Coriolis resonances determined from the observed perturbation effects on ν_1 and $\nu_2 + \nu_3$.

Ultraviolet Spectra of Nitryl Fluoride

The UV absorption spectrum of nitryl fluoride was quantitatively studied over the near-UV/visible region at room temperature [590]. The absorption obeyed Beer's law and was a continuum, having photoabsorption cross-sections (σ) ranging from $(2.2 \pm 0.8) \times 10^{-18}\text{ cm}^2$ at 195 nm to $(3.0 \pm 2.8) \times 10^{-20}\text{ cm}^2$ at 300 nm. No appreciable absorption ($\sigma < (3 \pm 3) \times 10^{-20}\text{ cm}^2$) occurred at wavelengths longer than 300 nm.

6.2.2.4 Microwave Spectra of Nitryl Fluoride

Microwave spectra of isotopically labeled molecules of NO_2F ($^{14}\text{N}^{16}\text{O}_2\text{F}$, $^{14}\text{N}^{18}\text{O}^{16}\text{OF}$, and $^{15}\text{N}^{16}\text{O}_2\text{F}$) gave rotational constants from the three species, which could then be used to determine the structure in several ways, resulting in angle $\angle\text{ONO} = 136^\circ \pm 1.5^\circ$, N—O distance = $1.1798 \pm 0.0035\text{ \AA}$, N—F distance = $1.467 \pm 0.015\text{ \AA}$, and O—O distance = $2.1878 \pm 0.003\text{ \AA}$, dipole moment $0.466 \pm 0.005\text{ D}$ [591].

The millimeter microwave rotational spectrum of NO_2F has been measured in the frequency range 90–200 GHz, and a complete set of the ground-state moments of inertia was obtained [592]. Two different methods were used in order to determine the general quadratic force field by a combination of IR and microwave data. The first method was based on the complete consistency between force constants and vibration frequencies of the normal species and on the best fit of the rotational spectrum. The second method used the least-squares determination of the corrections on some starting set of force constants. The two methods gave very similar results. The agreement between observed and calculated rotational and vibration frequencies was satisfactory.

Microwave spectra of NO_2F in excited vibrational states in the $\nu_3 = 1$ and $\nu_6 = 1$ states were identified, and the rotational constants, vibrational-rotational interaction constants, and inertia defects in these states were determined [593]. Large inertia defects and large vibrational-rotational interaction constants indicated that the ν_3 and ν_6 state vibrations are nearly degenerate. See also [594].

6.2.2.5 Molecular Structure of Nitryl Fluoride

Nitryl fluoride O_2NF is an isomer of nitrosyl hypofluorite ONOF , CAS RN [96607-23-7]. Nitrosyl hypofluorite is an unstable molecule, and its existence was contested for a long time.

The stretching-force constants of FNO_2 and ClNO_2 that were obtained in two different systems of symmetry coordinates were shown to be physically incompatible and need to be reexamined [595].

A series of self-consistent field–molecular orbital (SCF-MO) calculations using the method of linear combination of Gaussian-type functions (GTF) were performed on the nitryl fluoride molecule, and a variable geometry was used in order to obtain an *ab initio* potential hypersurface [596]. This hypersurface was used to obtain harmonic force constants for a matrix calculation, from which the fundamental frequencies associated with the normal modes were then calculated.

The in-plane harmonic and some cubic force constants of FNO_2 calculated by *ab initio* methods were compared with experimental data [597]. One of the two sets of equivalent force fields was physically correct but still reproduced isotope shift data poorly. Therefore, a new force field was determined that agreed with the *ab initio* results. Total and orbital energies and the dipole moment of FNO_2 were also calculated.

SCF-MO calculations were performed on three FNO_x ($x = 1, 2, 3$) compounds to obtain dipole moments, ionization potentials, and geometries [598]. The predicted relative stability for FNO_2 isomers was $\text{FNO}_2 > \text{cis-FONO} > \text{trans-FONO}$. FONO_2 was predicted to only slightly prefer a planar configuration, in agreement with experiments. The FONO_2 isomer was more stable than FOONO by about 167 kJ/mol (40 kcal/mol).

Computational chemistry with local density functional theory can predict some of the properties of FNO_2 . It was shown that FNO_2 is 171 kJ/mol (40.8 kcal/mol) more stable than *cis*- ONOF , which in turn is 105 kJ/mol (25.2 kcal/mol) more stable than its *trans* isomer [599].

It was found that the second-order Møller-Plesset (MP2) level of theory for the molecule of FNO_2 significantly overestimated the N–F bond length, which is the geometric parameter most sensitive to the effects of basis set and electron correlation [600]. More accurate structures were obtained by using the Pople split valence rather than Dunning-Huzinaga basis sets, a result explained by the compactness of the Pople basis sets. However, the use of the Pople basis sets did not overcome the deficiencies of the MP2 method for determining the structure and force field of FNO_2 . See also [601].

6.2.2.6 Thermodynamic Properties of Nitryl Fluoride

The standard enthalpy of formation of NO_2F has been determined by several authors, but the data do not agree very well. The direct synthesis reaction for NO_2F yielded a heat of formation value for the gas of -107.9 ± 2.1 kJ/mol (-25.8 ± 0.5 kcal/mol) [570].

IR and mass spectra of nitryl fluoride have been measured and serve as analytical tools or can be used to calculate thermodynamic data. The following thermodynamic data of nitryl fluoride in Table 21 were calculated from its IR spectra [602].

Table 21: Thermodynamic properties of nitryl fluoride.

Temperature K	Molar heat capacity		Enthalpy function		Free-energy function		Entropy	
	J mol ⁻¹ K ⁻¹	cal mol ⁻¹ °C ⁻¹	J mol ⁻¹ K ⁻¹	cal mol ⁻¹ °C ⁻¹	J mol ⁻¹ K ⁻¹	cal mol ⁻¹ °C ⁻¹	J mol ⁻¹ K ⁻¹	cal mol ⁻¹ °C ⁻¹
100	33.9	8.11	33.3	7.97	183.7	43.90	217.0	51.87
200	41.3	9.86	35.2	8.42	207.2	49.52	242.5	57.95
273	47.8	11.42	37.7	9.02	218.5	52.23	256.3	61.25
293	49.5	11.82	38.5	9.19	221.2	52.87	259.7	62.07
303	50.3	12.02	38.9	9.29	222.2	53.11	261.1	62.40
400	57.1	13.64	42.5	10.15	233.8	55.88	276.3	66.03
500	62.3	14.90	45.9	10.98	243.6	58.23	289.6	69.22
600	66.4	15.88	49.0	11.72	252.3	60.30	301.3	72.02
700	69.5	16.62	51.7	12.36	260.0	62.15	311.7	74.51
800	71.9	17.19	54.1	12.93	267.1	63.83	321.2	76.76
900	73.8	17.64	56.2	13.43	273.6	65.39	329.8	78.82
1000	75.2	17.98	58.0	13.87	279.6	66.83	337.6	80.70

Data source: [602]

These data agreed essentially with those reported by Tschuikow-Roux: The thermodynamic data of nitryl fluoride were calculated according to the rigid rotator harmonic oscillator approximation [603]. The bond energy of the N—O bond was 256 kJ/mol (61.3 kcal/mol), and the bond energy of the N—F bond was 187 kJ/mol (44.7 kcal/mol). See also [604].

The gas-phase heat capacity of NO₂F can be calculated by a Shomate equation

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + \frac{E}{\tau^2}$$

where C_p is the heat capacity in J mol⁻¹ K⁻¹; τ is the temperature in kelvin divided by 1000: $\tau = K/1000$; and A, B, C, D, and E are constants listed in Table 22 for two temperature ranges. According to the NIST Chemistry WebBook website, the standard enthalpy of formation of the NO₂F gas is ΔH_f^{298} gas (−108.78 kJ/mol). The enthalpy of formation of gaseous NO₂F as a function of temperature can be expressed by the equation

$$H^\circ - H_{298.15}^\circ = A\tau + \frac{B\tau^2}{2} + \frac{C\tau^3}{3} + \frac{D\tau^4}{4} - \frac{E}{\tau} + F - H$$

where H° is the standard enthalpy in J mol^{-1} ; τ is the temperature in kelvin divided by 1000: $\tau = K/1000$; and A, B, C, D, E, F, and H are constants listed in Table 22 for two temperature ranges. The standard entropy of gaseous NO_2F as a function of temperature can be expressed by the equation

$$S^\circ = A \times \ln(\tau) + B\tau + \frac{C\tau^2}{2} + \frac{D\tau^3}{3} - E/(2\tau^2) + G$$

where S° is the standard entropy in $\text{J mol}^{-1} \text{K}^{-1}$; τ is the temperature in kelvin divided by 1000: $\tau = K/1000$; and A, B, C, D, E, and G are constants listed in Table 22 for two temperature ranges.

Table 22: Coefficients for thermodynamic property Shomate equations for nitryl fluoride.

Temperature range (K)	298–1100	1100–6000
A	25.78490	81.12650
B	112.9375	1.116488
C	-89.46061	-0.224392
D	26.17284	0.015461
E	-0.208291	-6.925650
F	-121.4527	-150.8014
G	260.3523	332.9213
H	-108.7840	-108.7840

Data source: [132]

6.2.3 Chemical Properties of Nitryl Fluoride

Nitryl fluoride is a potential intermediate in the photolysis and destruction of ozone layer-depleting fluorocarbons in the upper atmosphere; consequently, some work has been done on the photolysis and kinetics of atmospheric reactions of atomic oxygen and ozone involving FNO_2 [605].

Very few investigations have been reported on the hypergolic ignition of FNO_2 with amines and hydrazines, propellant combinations that deserve further study.

6.2.3.1 Thermal Decomposition of Nitryl Fluoride

At temperatures above 293 K (+20 °C), nitryl fluoride dissociates partially into nitrogen dioxide and difluorine. Therefore, it is difficult to measure IR spectra of the pure vapor without interference by NO_2 .

6.2.3.2 Reactions of Nitryl Fluoride with Inorganic Compounds

Nitryl fluoride is a strong oxidizer that will spontaneously ignite with iodine, antimony, arsenic, phosphorus, boron, silicon, and many organic compounds, and it reacts with hydrogen, sulfur, mercury, and charcoal only at elevated temperature.

Quartz glass will not be attacked by dry nitryl fluoride. Nitryl fluoride can be mixed with oxygen difluoride without reaction [606].

Instead of storing nitryl fluoride as a cryogenic liquid or compressed gas, it is more convenient to store it in the form of its stable, solid complex salts $[\text{NO}_2][\text{BF}_4]$ or $[\text{NO}_2][\text{PF}_6]$ and to release it on demand by reaction with sodium fluoride.

^{14}N or ^{15}N NMR and electrical conductivity measurements have indicated conclusively that NO_2F is completely dissociated into NO_2^+ and F^- ions when it is dissolved in liquid H_2F_2 [607]. The existence of the equilibrium

was demonstrated by the magnetic resonance shift of ^{14}N in HNO_3/HF mixtures.

The phase diagram of the system $\text{NO}_2\text{F}\text{-HF}$ showed the formation of the following four addition compounds: $\text{NO}_2\text{F}\cdot 3.50\text{HF}$, $\text{NO}_2\text{F}\cdot 4.00\text{HF}$, $\text{NO}_2\text{F}\cdot 5.25\text{HF}$, and $\text{NO}_2\text{F}\cdot 6.66\text{HF}$ [608]. The diagram, which contained five eutectics, resembled that of the system $\text{NOF}\text{-HF}$. An addition compound with the composition of $\text{NO}_2\text{F}\cdot 5\text{HF}$ is a water-like liquid with a freezing point below 195 K (-78°C).

6.2.3.3 Reactions of Nitryl Fluoride with Organic Compounds

Nitryl fluoride would be suitable as a hypergolic oxidizer because it ignites spontaneously with all amines and hydrazines. Experimental results have not been reported.

6.2.4 Toxicity of Nitryl Fluoride

Nitryl fluoride has a pungent odor and attacks the mucous membranes vigorously.

6.3 Nitroxyl Fluoride

Nitroxyl fluoride, NO_3F (also improperly called “fluorine nitrate”), CAS RN [7789-26-6], was discovered by Cady in 1934 when he reacted difluorine with 3-N nitric acid [609]. Frequent explosions occurred during its preparation and even more so during subsequent experiments to determine its physical and chemical properties [610]. The colorless liquid boils at 231 K (-42°C) and hydrolyzes rapidly, even with traces of moisture. Due to its explosive properties, this compound is not suitable as a rocket propellant, although it would probably ignite hypergolically with most commonly used fuels.

6.3.1 Preparation of Other Nitroxyl Halogenides

Halogen analogues of nitroxyl fluoride, chlorine nitrate, and bromine nitrate are more stable than nitroxyl fluoride but still need to be handled with caution.

Chlorine nitrate can be made from chlorine monofluoride and nitric acid [611]:

The reaction of BrF_5 with a large excess of LiNO_3 at 273 K (0°C) produced BrONO_2 , LiF , N_2O_5 , and O_2 as the principal products [612]. BrONO_2 has a planar structure. With N_2O_5 , the BrONO_2 molecule formed an unstable adduct, which was shown by Raman spectroscopy to possess the ionic structure $\text{NO}_2^+[\text{Br}(\text{ONO}_2)_2]^-$. A cesium salt $\text{Cs}^+[\text{Br}(\text{ONO}_2)_2]^-$ was also prepared, and its vibrational spectra were recorded and assigned. Bromine nitrate may play a role in atmospheric chemistry and ozone depletion.

6.3.2 Physical Properties of Nitroxyl Fluoride

Nitroxyl fluoride is a colorless liquid that boils at 231 K (-42°C).

6.3.2.1 Optical Properties of Nitroxyl Fluoride

The low-temperature IR and Raman spectra of $\text{I}(\text{NO}_3)_3$ and the Raman spectra of liquid ClONO_2 , FONO_2 , FNO_2 , and ClNO_2 have been recorded [613]. Comparison of the vibrational spectra within the series NO_2 , FNO_2 , ClNO_2 , FONO_2 , and ClONO_2 allowed unambiguous assignments for the halogen nitrate molecules. Raman polarization measurements showed that in halogen nitrates, the halogen atom is perpendicular to the ONO plane, contrary to previous assumptions, and to the known planar structure of HONO_2 and CH_3ONO_2 . The vibrational spectrum of $\text{I}(\text{NO}_3)_3$ is consistent with predominantly covalent nitrate ligands. However, the complexity of the spectrum suggests a polymeric structure with bridging nitrate groups.

The vibrational frequencies and corresponding normal mode assignments of nitroxyl fluoride were examined theoretically using the Gaussian 98 set of quantum chemistry codes [614]. All normal modes were successfully assigned to one of six types of motion utilizing the C_s symmetry of the molecule. Uniform scaling factors were derived for each type of motion. Predicted IR and Raman intensities agreed well with reported experimental measurements.

6.3.2.2 Molecular Structure of Nitroxyl Fluoride

The molecular structure of nitroxyl fluoride was the subject of lengthy disputes for several decades. Eventually the experts agreed that nitroxyl fluoride has a planar structure similar to nitric acid and methyl nitrate. It oscillates between two isomeric structures:

A general valence force field for FONO_2 was derived from frozen Ne-matrix IR spectra together with ^{15}N and ^{18}O isotopic shifts [615]. A gas electron diffraction study resulted in a planar structure with the following geometric parameters (distances and

angles with 3σ uncertainties in parentheses): N=O 1.184(2) Å, N—O 1.507(4) Å, O—F 1.409(5) Å, $\angle$ O—N=O_c 117.1(9)°, $\angle$ O—N=O_t 108.4(18)°, $\angle$ O_c—N=O_t 134.5(21)°, and $\angle$ N—O—F 106.0(11)°. O_c and O_t are the oxygen atoms *cis* and *trans* to the O—F bond. The N—O single bond in fluorine nitrate is about 0.1 Å longer than those in nitric acid and methyl nitrate (Figure 8).

Figure 8: Molecular structures of nitroxyl fluoride.

The molecular structure of nitroxyl fluoride has been derived from IR and Raman spectra and discussed in terms of the adjacent charge rule [616].

6.3.2.3 Thermodynamic Properties of Nitroxyl Fluoride

The heat of formation of gaseous nitroxyl fluoride is $+10.46 \pm 2.1$ kJ/mol ($+2.5 \pm 0.5$ kcal/mol) [617, 618].

Another source reported the enthalpy of formation of gaseous nitroxyl fluoride at 294 K as -17.6 ± 3.8 kJ/mol (-4.2 ± 0.9 kcal/mol) [619, 620].

6.3.3 Chemical Properties of Nitroxyl Fluoride

Other known halogen nitrates are ClONO₂, and I(NO₃)₃. Nitroxyl fluoride is extremely shock sensitive. I(NO₃)₃ is a non-volatile residue in the form of a fluffy, light yellow solid that decomposes above 273 K (0 °C).

Nitroxyl fluoride decomposed explosively into NOF and O₂. The slow thermal decomposition over the range 353–380 K (80–107 °C) proceeded by a different stoichiometry [621]:

The first-order rate constant decreased with decreasing initial reactant pressure, showing a fall-off region characteristic of a unimolecular reaction. The rate constant was

$$k_\infty = 5.80 \times 10^{13} \exp(-29700/RT) \text{ s}^{-1}$$

See also [622, 623]. Nitroxyl fluoride reacted with tetrafluoroethylene to form carbonyl fluoride and trifluoronitromethane [610].

6.4 Trifluoramine Oxide

Trifluoramine oxide, also known as trifluoroamine oxide, F_3NO , nitrogen trifluoride oxide, nitrogen fluoride oxide, nitrogen oxide trifluoride, "AMOX", CAS RN [13847-65-9] was discovered in the early 1960s. In 1966 three research groups independently reported the synthesis of trifluoramine oxide, F_3NO [624–626], but the filing dates of some patents predate these publications. If nitrogen trifluoride is already a good rocket propellant oxidizer, then trifluoramine oxide should be an even better oxidizer because it contains additional oxygen. It would be much better if it were only more readily available. It has not yet flown in a rocket, and even static ground-level tests have not yet been reported.

6.4.1 Preparation of Trifluoramine Oxide

Trifluoramine oxide can be made by fluorination of nitric oxide or by pyrolysis of nitrosyl hexafluoronickelate(IV) or nitrosyl hexafluoroiridate(VI) [625]. At 760 mm Hg, 500 mL NOF gas and 2500 mL F_2 gas were condensed at 77 K (-196°C) into a reactor constructed of Ni or Monel, and the reactor was pressurized to 7.9 MPa (1150 psig) with N_2 and heated for 1 h at 623 K (350°C) as the pressure rose to 34 MPa (4950 psig) [627]. The reactor was then quickly chilled to 77 K (-196°C) and was vented, and the contents were fractionally distilled to give 97% F_3NO containing 1% NOF and some F_2 . Varying the conditions gave lower yields of F_3NO .

Trifluoramine oxide (nitrogen oxide trifluoride) was prepared in trace quantities by the reaction of nitric oxide and fluorine [628]. Low but improved yields were obtained when nitrosyl fluoride and fluorine were heated together at 493 K (220°C). It was found that $(\text{NO})_2\text{NiF}_6$ was formed by the reaction of the walls of the Monel reaction vessels with nitrosyl fluoride and fluorine and that pyrolysis of this salt (in 483 kPa [70 psi] fluorine at 623 K [350°C]) gave the new compound in good yield. The reactions of platinum and iridium hexafluoride with nitrosyl fluoride were also investigated as potential routes to ONF_3 . Trifluoramine oxide was colorless in the solid, liquid, and gaseous phases, melting at 112 K (-161°C) and boiling at 185.6 K (-87.5°). The vapor pressure was determined over the range 145–195 K (-128 to -78°C). Trifluoramine oxide was found to be only moderately reactive. There was no evidence that ONF_3 could be protonated by strong acids. A 1:1 adduct was formed with AsF_5 . The chemical behavior and IR spectrum of the adduct were consistent with the formula $[\text{ONF}_2^+][\text{AsF}_6^-]$.

The apparatus used for preparation of F_3NO was similar to that employed by Kirshenbaum for the low-temperature electric-discharge preparation of O_3F_2 [629]. In a typical run, an equimolar mixture (77 mmol each) of gaseous NF_3 and oxygen was

passed slowly at 10–15 mm pressure into the discharge tube (held at 77 K [–196 °C]) with continuous pumping on the exit side of the tube to remove non-condensable material and to maintain the reactor pressure in the desired range. During a run, which generally required 1–2 h, the discharge current varied from 30 to 50 mA at 5 kV. Upon completion of a run, the condensable material in the discharge tube was an amber solid–liquid mixture at 77 K (–196 °C) that became a reddish liquid on slight warming. Alternate warming to 195 K (–78 °) and cooling to 75 K (–198 °C) caused all color to disappear and produced considerable non-condensable off-gassing, suggesting that the colored materials were lower-oxygen fluorides (e.g., O_2F_2 or O_3F_2) that decomposed to O_2 and F_2 . Subsequent fractionation through traps at 140, 90, and 77 K (–130, –183, and –196 °C) yielded unreacted NF_3 (23.3 mmol, trapped at 77 K [–196 °C]), F_3NO (7.0 mmol, trapped at 90 K [–183 °C]), and an unresolved mixture (trapped at 140 K [–130 °C]) of NO_2 , N_2O_3 , and a white solid that was probably $(\text{NO})_2\text{SiF}_6$. From these data, the conversion of NF_3 was 71%, and the yield of F_3NO was 13%.

Trifluoramine oxide can be obtained readily by the photochemical fluorination of nitrosyl fluoride at ambient temperature and pressure [630, 631]:

Although the direct fluorination of nitrosyl fluoride had been attempted before, F_3NO was produced only at high temperature and pressure where corrosive attack on the reactor was severe. Other methods for F_3NO synthesis required either relatively complex electric-discharge apparatus or the use of higher-valent transition metal fluorides (IrF_6 , OsF_6) that are difficult and inconvenient to prepare. The photochemical method produced 50% yields of F_3NO and required only simple apparatus and the readily available raw materials fluorine and nitric oxide.

The effluent from a F_2/NO flame contained traces of F_3NO , suggesting that the very exothermic initial reactions provided the energy necessary for further fluorination of NOF [632]. Rapidly quenching the energy-rich gas mixture in the flame by impinging on a cold surface increased the yield of F_3NO , and further enhancement resulted when F_2 in excess of that required for NOF formation was used. A convenient, continuous-flow process was developed for F_3NO synthesis in yields up to 20% by using the empirically optimized reactor geometry, reactant ratio, gas flow rates, and quench temperature conditions.

Trifluoramine oxide can be prepared by reacting air with fluorine or fluorine with nitrogen oxides in a glow discharge and quenching the reaction products on a cold finger [633]. Trifluoramine oxide can be prepared by reacting difluoramine with chlorine trifluoride and an oxygenated halogen compound such as ClO_2 , FClO_2 , or FClO_3 [634–636]. The reaction between difluoramine, chlorine trifluoride, and the oxygenated halogen compound is conducted in the gas phase. The gaseous reactants are cooled to a condensed phase in separate layers at temperature below 147 K (–126 °C). After the reactants are condensed, the temperature is raised to above 147 K (–126 °C), and the gas-phase reaction allowed to proceed at temperatures between 147

and 303 K (–126 and +30 °C). The product and by-products have to be separated by multiple fractionated condensation.

The formerly difficult synthesis of F_3NO has been facilitated by the direct chemical oxygenation of NF_3 . The interaction of NF_3 with N_2O in the presence of SbF_5 at 423 K (150 °C) leads to the quantitative formation of the previously known $[NOF_2]^+[Sb_2F_{11}]^-$ salt. Vacuum pyrolysis of $[NOF_2]^+[Sb_2F_{11}]^-$ at 463–503 K (190–230 °C) in the presence of excess NaF affords NOF_3 in high yield.

The operation of a microwave cavity and electrodeless discharge cell filled with mixtures of O_2 , N_2 , and F_2 and immersed in liquid nitrogen produced small amounts of ONF_3 [637]. Higher yields of ONF_3 were produced by a capacitor pulsed discharge between electrodes in a low-temperature cell, but yields were very low if a direct-current discharge was used.

At low temperatures and ambient pressures, $ClFO_3$ and HNF_2 react to form ONF_3 , $ClNF_2$, and HF [638]. Higher yields can be obtained at autogenic pressures. The reactor was evacuated and cooled to condense one of the reactants, the other reactant was added, and, as the cooling means was removed, the reaction proceeded. Thus, 30 cm³ $ClFO_3$ was condensed at 77 K (–196 °C). Then 29 cm³ HNF_2 was condensed in the same trap at 131 K (–142 °C), and the reaction was allowed to proceed. All of the HNF_2 was converted to a 2:2:1 mixture of NF_3O , $ClNF_2$, and N_2F_4 .

F_2 can react with N_2O in a glow discharge to form ONF_3 [639]. A mechanism of the reaction was proposed involving the formation of NO and atomic F as intermediates. At a $F_2:N_2:O_2 = 3:1:1$ concentration ratio, O_2F_2 formation would compete with ONF_3 formation. This was attributed to a faster reaction of atomic F with O_2 than that with NO and to O_2F_2 stabilization along the cold-reaction vessel walls. ONF_3 can be purified by filtering it through a bed of dry, solid KOH.

Equilibrium compositions of the N-O-F system were calculated as a function of temperature (200–1000 K) and pressure (20–760 mm Hg) [640]. Variation of concentrations was shown for 10 of 26 species present in this system. Optimum concentration of NF_3 occurred at 200–300 K. The concentration of ONF_3 decreased rapidly as the temperature increased. The yield of ONF_3 depends on the type of electrical discharge and the quenching conditions.

6.4.2 Physical Properties of Trifluoramine Oxide

Trifluoramine oxide has a melting point of 111.6 K (−161.5 °C) and a boiling point of 184 K (−89 °C). The vapor pressure of trifluoramine oxide can be expressed by the equation [629]

$$\log P = -A + \frac{B}{T} + \frac{C}{T^2} + D \log T$$

where P is the vapor pressure in mm Hg, T is the temperature in kelvin, and the constants A , B , C , and D are as follows: $A = 10.391602$, $B = 180.04119$, $C = 39443.176$, and $D = 6.0353102$. The normal boiling point from the equation is 185.5 K (−87.6 °C), Trouton's constant is 20.7, and the heat of vaporization is 16.1 kJ/mol (3.85 kcal/mol). The critical temperature is 302.6 K (29.5 °C), the critical density is 0.593 g/cm³, and the critical pressure is 63.5 atm. The temperature dependence of liquid density over the range 193–153 K (−80 to −120 °C) is

$$d = 1.237 - 0.003544t$$

where t is the temperature in degrees Celsius and d is the density in g/cm³. See also [13].

6.4.2.1 Optical Properties of Trifluoramine Oxide

Infrared Absorption Spectra of Trifluoramine Oxide

Trifluoramine oxide gas exhibits strong IR absorptions at 530, 743, 885, 1690, and 1771 cm^{−1}. The IR spectrum of F₃NO is shown in Figure 9.

Figure 9: Infrared spectrum of trifluoramine oxide. (Reproduced and modified from [636].)

The general appearance of the IR spectrum established that the NF_3O molecule has C_{3v} symmetry [641]. The bands at 1691, 743, 528, 883, 558, and 400 cm^{-1} were assigned as the fundamental frequencies. The rotational spacing of ν_2 was used to determine the rotational constant, $B = 0.19\text{ cm}^{-1}$. Assuming tetrahedral angles and $r(\text{N}-\text{O}) = 1.15\text{ \AA}$ with this rotational constant gave an estimate of $r(\text{N}-\text{F}) = 1.48\text{ \AA}$.

The IR spectra of trifluoramine oxide and its ^{15}N analogue have been measured from 4000 to 260 cm^{-1} , and fundamental frequency assignments (based upon C_{3v} symmetry) were made from the ^{14}N spectrum as follows: $\nu_1(\text{a}_1) = 1689\text{ cm}^{-1}$, $\nu_2(\text{a}_1) = 740\text{ cm}^{-1}$, $\nu_3(\text{a}_1) = 528\text{ cm}^{-1}$, $\nu_4(\text{e}) = 880\text{ cm}^{-1}$, and $\nu_6(\text{e}) = 398\text{ cm}^{-1}$ [642]. Normal coordinate calculations support the assignment of the remaining fundamental $\nu_5(\text{e})$ to a band system appearing as a shoulder, about 558 cm^{-1} , on the intense $\nu_3(\text{a}_1)$ fundamental.

An investigation of the partially resolved IR bands of NOF_3 in the region 350 – 1800 cm^{-1} provided the rotational constant B_0 , the Coriolis constants, and integrated absorption intensities [643].

Raman Fluorescence Spectra of Trifluoramine Oxide

The Raman spectrum of a polycrystalline film of ONF_3 at 78 K was measured with displacements of 90 – 2500 cm^{-1} from the exciting line from a 60-mW helium-neon laser [644]. The vapor pressure of the solid sample at this temperature was 0.053 Pa ($8 \times 10^{-4}\text{ mm Hg}$), making the sample preparation rather difficult, which compromised the quality of the observed spectrum.

The main feature in the Raman spectrum of gaseous F_3NO was the band structure between 500 and 550 cm^{-1} [645]. The sharp bend occurring at 542 cm^{-1} was definitely polarized, while the band at 528 cm^{-1} was depolarized. These were therefore assigned as $\nu_3(\text{A}_1)$ and $\nu_3(\text{E})$, respectively, in conformance with earlier assignments. See also [646].

Raman spectra of ONF_3 were recorded from 118 to 300 K and, as predicted through group theory for C_{3v} mol, ONF_3 has six fundamental frequencies that are all Raman and IR active: three A_1 bands ($\nu_1 \sim 1680\text{ cm}^{-1}$, NO symmetric stretch; $\nu_2 \sim 740\text{ cm}^{-1}$, NF symmetric stretch; $\nu_3 \sim 540\text{ cm}^{-1}$, NF δ symmetry), and three E-type bands ($\nu_4 \sim 880\text{ cm}^{-1}$, NF asymmetric stretch; $\nu_5 \sim 530\text{ cm}^{-1}$, NOF deformation; $\nu_6 \sim 400\text{ cm}^{-1}$, NF δ symmetry) [647].

The rotational behavior of NOF_3 was derived from the band contour analysis of the Raman spectra in the liquid phase [648]. The angular momentum correlation times derived from the rotational diffusion model indicated that the molecule rotates almost isotropically. The band profiles were interpreted in terms of the rough hard-sphere model.

Ultraviolet Absorption Spectra of Trifluoramine Oxide

The UV spectrum of F_3NO showed an onset of very weak absorption at $2200\text{ \AA}$, the intensity increasing only slightly down to the limit of measurement at $2800\text{ \AA}$. Prolonged

photolysis of F_3NO gas in a nickel cell with BaF_2 windows with a 500-W high-pressure mercury lamp caused only minor decomposition, with traces of NO_2 , NO_2F , and NOF being formed.

Microwave Spectra of Trifluoramine Oxide

The microwave spectrum of ONF_3 cooled to 195 K (-78°C) gave a symmetric rotor pattern that was consistent with the point group C_{3v} assignment [649]. The dipole moment was very small, 0.0390 ± 0.0004 D, which made it difficult to record the microwave spectrum.

6.4.2.2 Magnetic Properties of Trifluoramine Oxide

The ^{14}N NMR shift in ONF_3 at 153 K was +376 ppm in relation to the shift in aqueous nitrite ion [193].

6.4.2.3 Molecular Structure of Trifluoramine Oxide

Several possible molecular structures for trifluoramine oxide are shown in Figure 10.

Figure 10: Possible molecular structures for trifluoramine oxide.

The nearly tetrahedral C_{3v} symmetry of F_3NO is clearly supported by the IR spectrum in which the required six fundamental bands have been assigned. The N—O stretching vibration at 1687 cm^{-1} in F_3NO is closer to that of an $\text{N}=\text{O}$ double bond than to that of the familiar amine N-oxides and, in fact, has nearly 75% double-bond character.

The molecular structure of trifluoramine oxide is illustrated in Figure 11.

Figure 11: Molecular structures for trifluoramine oxide.

With the experience with organic amine N-oxides, one would first assume that nitrogen trifluoride oxide NF_3O is an amine N-oxide, but it behaves quite different from or-

ganic amine N-oxides. The bonds are highly covalent, and it has a low freezing point and low boiling point compared to organic N-oxides. Nitrogen trifluoride oxide, NF_3O , is a fascinating molecule that is isoelectronic with NF_4^+ . Its N—O bond possesses a high degree of double-bond character ($r_{\text{N—O}} = 1.159 \text{ \AA}$); therefore, it is not a typical amine oxide with a long, semipolar $\text{N} \rightarrow \text{O}$ bond and a negative charge on the oxygen atom.

Trifluoramine oxide does not contain an N—O—F bond as originally assumed. The N—F and N—O bond-lengths of 1.43 and 1.15 Å for this molecule are, respectively, longer than the N—F bonds of NF_3 and NF_4^+ (1.36 and 1.30 Å) and similar to the bond length (1.15 Å) for free NO. Resonance between several structures can account qualitatively for the lengthening of the N—F bond. Nitrogen difluoride hypofluorite (difluoroaminohypofluorite, CAS RN [14984-90-8]) F_2NOF is unstable and would rearrange itself to trifluoroamine.

Several values of force constants, mean amplitudes of vibration, and thermodynamic functions of ONF_3 were calculated [650]. The diagonal symmetry force constants, internal coordinate force constants, and mean vibrational amplitudes were listed in the report. The enthalpy per degree kelvin, the free enthalpy per degree, the entropy, and the heat capacity for the ideal gas at 1 atm pressure in $\text{cal } ^\circ\text{C}^{-1} \text{ mol}^{-1}$ are, respectively, as follows: at 273.16 K, 10.51, 54.42, 64.93, 15.40; at 298.16 K, 10.95, 55.36, 66.31, 16.22. Similar values were given for 19 other temperatures in the region 200–2000 K.

The molecular structure of trifluoramine oxide has been investigated by gaseous electron diffraction at a nozzle temperature of 293 K (20 °C) [651]. The results verified the expected C_{3v} symmetry for the molecule. The N—F bond is slightly longer than the sum of the single-bond radii corrected for electronegativity difference, but the N—O bond is very much shorter and must be regarded as essentially a double bond. The bond angles were not in themselves unusual. However, the positions of the four ligands corresponded with remarkable accuracy to the corners of a regular tetrahedron, a fact that strongly emphasizes the importance of non-bonded interactions. The five covalent bonds formed by the nitrogen atom may be understood in terms of a σ system of four bonds comprising 2s-2p hybrids and a π -bond obtained by utilizing an empty 3p π or 3d π nitrogen orbital with a filled 3p π oxygen orbital. The distances and amplitudes are r_a and l_a values. The electron-diffraction analysis led to the following values for the principal parameters: $r(\text{N}=\text{O}) = 1.158 \text{ \AA}$, $r(\text{N}-\text{F}) = 1.431 \text{ \AA}$, $r(\text{O}-\text{F}) = 2.214 \text{ \AA}$, $r(\text{F}\cdots\text{F}) = 2.206 \text{ \AA}$, $l(\text{N}=\text{O}) = 0.0289 \text{ \AA}$, $l(\text{N}-\text{F}) = 0.0507 \text{ \AA}$, $l(\text{O}\cdots\text{F}) = 0.0584 \text{ \AA}$, $l(\text{F}\cdots\text{F}) = 0.0551 \text{ \AA}$, $\angle \text{ONF} = 117.1^\circ$, and $\angle \text{FNF} = 100.8^\circ$.

The photoelectron spectrum of F_3NO showed evidence for four ionization potentials [652].

The electronic structure and conformation of ONF_3 were investigated based on complete neglect of differential overlap (CNDO) and intermediate neglect of differential overlap (INDO) approximations [653]. The minimization of the total energy with respect to the ONF angle occurred for a value that agreed perfectly with microwave

data. A bicentric energy partitioning showed that the variations of the total energy were completely reflected by the only variation of the N—F bond energy. The analysis of electronic density revealed the importance of the $2s(\text{N}) \rightarrow 2px(\text{O})$ transfer in the formation of the dative ($\text{N} \rightarrow \text{O}$) bond, the total transfer being equal to 0.33 electrons.

A normal coordinate analysis of the force field in ONF_3 gave good agreement between calculated and observed fundamental frequencies of this molecule, both for O^{14}NF_3 and for O^{15}NF_3 [654].

The potential energy constants of ONF_3 were evaluated on the basis of the general valence force field theory [655]. The mean-square amplitudes of vibration, the generalized mean-square amplitudes of vibration, Coriolis coupling constants, shrinkage constants, and rotation distortion constants of this molecule were also computed.

The oxygen, nitrogen, and fluorine core-binding energies of ONF_3 have been re-determined. The data indicated strong hyperconjugation, with N—O π -bonding and weak N—F σ -bonding [656]. The core and valence ionization potentials together indicated that the highest occupied molecular orbital (HOMO) of ONF_3 (derived mainly from the O p π orbitals) is weakly anti-bonding. This result was consistent with other data if it was assumed that the latter orbital has considerable fluorine lone-pair character and that the orbital derived mainly from the N—F σ orbitals (at lower energy) has considerable N—O π character.

To avoid exceeding eight valence electrons on nitrogen and to satisfy the high electronegativity of fluorine, the NF_3O molecule is best described as an $\text{F}_2\text{NO}^+\text{F}^-$ type structure in which the negative charge is evenly distributed over all three fluorine ligands. This assumption is supported by the unusually long (1.432 Å) and polar N—F bonds observed for NF_3O [657].

6.4.3 Chemical Properties of Trifluoramine Oxide

Trifluoramine oxide is a strong oxidizing agent toward many organic and inorganic materials but is resistant to hydrolysis, even by strong aqueous bases. The latter property is useful in purification, since common impurities (SiF_4 , NO_2 , NOF , NO_2F) are easily removed by scrubbing with strong aqueous KOH solution without significant loss of F_3NO . Carefully purified F_3NO is stable in glass and most metals at 298 K (25 °C).

6.4.3.1 Thermal Decomposition of Trifluoramine Oxide

Trifluoramine oxide gas may be heated to 573 K (300 °C) (atmospheric pressure) for short periods in nickel or Monel without change, but prolonged heating (longer than 1–2 h) caused increasing degradation to nitrosyl fluoride and secondary products (NO_2 , NO_2F , NO). It never decomposed to NF_3 and O_2 .

At temperatures above 523 K (250 °C), F_3NO is known to form an equilibrium with FNO and F_2 that, in the presence of SbF_5 , is continuously shifted to the FNO and F_2 side by the formation of the stable NOSbF_6 and NF_4SbF_6 salts.

6.4.3.2 Photolysis of Trifluoramine Oxide

Gases passing through the inlet of a mass spectrometer are usually ionized by electron bombardment, but they can also be ionized by UV radiation. If the wavelength of the UV radiation is varied, coming from the long-wavelength end of the spectrum until first ionization is detected, this photolysis/mass spectrometry method can be used to determine the bond strengths of the bonds being broken. Photoionization yield curves for the ONF_3^+ , ONF_2^+ , and NO^+ ions of NF_3O were measured from the threshold to 600 Å [227]. The ionization energies were used to calculate heats of formation of the ions, ionization energies of radicals, and bond dissociation energies. The heat of formation of ONF_3 was $-3.02\text{ eV} = -69.6\text{ kcal/mol} = -291\text{ kJ/mol}$, and the dissociation energy $D(\text{O}-\text{NF}_3)$ was 4.3 eV and $D(\text{ONF}_2-\text{F})$ was 1.9 eV.

After about 60 min of exposure of trifluoramine oxide in an argon matrix at 8 K to UV radiation of wavelengths 240–400 nm, the resultant F_3NO spectrum was essentially unchanged [658]. However, after a similar period of exposure (65 min) to photolytic UV radiation of wavelengths 220–900 nm, the IR features of NOF began to appear.

Photolysis of solid F_3NO at 77 K (-196°C) produced the F_2NO radical, which was identified by its nine-line ESR spectrum consisting of a fluorine split 1:2:1 triplet ($a\text{F} = 143.0\text{ G}$), each component of which was further split by ^{14}N into 1:1:1 triplets ($a\text{N} = 94.5\text{ G}$), with $g = 2.0093$ [659]. The data were best interpreted in terms of a pyramidal structure for F_2NO .

6.4.3.3 Reactions of Trifluoramine Oxide

Reactions of Trifluoramine Oxide with Inorganic Substances

Trifluoramine oxide forms stable 1:1 complexes with the Lewis acids AsF_5 and SbF_5 . These complexes are ionic $[\text{F}_2\text{NO}^+][\text{MF}_6^-]$ because the ^{19}F NMR spectrum of each in HF solution showed a 4:5:4 triplet N–F resonance at $\delta_{\text{FCCl}_3} = -331 \pm 3\text{ ppm}$ along with the high-field resonance of the corresponding MF anions.

Trifluoramine Oxide can form white crystalline 1:1 adducts with the Lewis acids BF_3 , AsF_5 , and SbF_5 [660]. In addition to the 1:1 compound, BF_3 can form at 147 K (-126°C) a 2:1 adduct with NF_3O . The thermal stability of these complexes decreased in the order of $\text{NF}_3\text{O}\cdot\text{SbF}_5 > \text{NF}_3\text{O}\cdot\text{AsF}_5 > \text{NF}_3\text{O}\cdot\text{BF}_3 > \text{NF}_3\text{O}\cdot 2\text{BF}_3$. The dissociation pressure–temperature relation has been measured, and thermodynamic data were calculated for the process

Hydrolysis of $\text{NF}_3\text{O}\cdot\text{AsF}_5$ resulted in the formation of $\text{NO}_2^+\text{AsF}_6^-$. IR and Raman measurements showed that $\text{NF}_3\text{O}\cdot\text{SbF}_5$, $\text{NF}_3\text{O}\cdot\text{AsF}_5$, $\text{NF}_3\text{O}\cdot\text{BF}_3$, and $\text{NF}_3\text{O}\cdot 2\text{BF}_3$ have the ionic structures $[\text{NF}_2\text{O}^+][\text{SbF}_6^-]$, $[\text{NF}_2\text{O}^+][\text{AsF}_6^-]$, $[\text{NF}_2\text{O}^+][\text{BF}_4^-]$, and $[\text{NF}_2\text{O}^+][\text{B}_2\text{F}_7^-]$, respectively. The $[\text{NF}_2\text{O}^+]$ cation (point group C_{2v}) has a structure similar to that of the isoelectronic CF_2O [661].

Trifluoramine oxide oxidized N_2F_4 , N_2O_4 , Cl_2 , or SF_4 to NF_3 , NO_2F , ClF , or SF_6 , respectively, the F_3NO being reduced to NOF in each case [662]. These and other reaction studies indicated that oxidations by F_3NO involve primarily fluorination rather than oxygenation. Trifluoramine oxide was not readily hydrolyzed by water or aqueous base but was attacked by sulfuric acid.

Trifluoramine oxide was found to react rapidly with nitric oxide to give nitrosyl fluoride (FNO) [663]. A free-radical reaction involving the known difluoronitryl (F_2NO) radical was proposed as a plausible mechanism.

Gaseous F_2NO^+ cations have been obtained from the ionization of a $\text{F}_2\text{N}^+/\text{N}_2\text{O}$ mixture under typical chemical ionization conditions [664]. The F_2NO^+ cations originate from the ion-molecule reaction

the occurrence of which has been ascertained by FTIR experiments.

Reactions of Trifluoramine Oxide with Organic Substances

Trifluoramine oxide reacts readily with a variety of amines to form the corresponding N-fluoro and N-nitroso derivatives in good yields [665]. A number of metals, including Ga, Sn, and Sb, are rapidly converted to GaF_3 , SnF_4 , or SbF_5 .

Trifluoramine oxide enabled the selective fluorination of haloolefins [666] and polyfluoroalkyl ethers [667]. NF_3O -Lewis acid complexes were studied by NMR spectroscopy [668]. Reactions of ONF_3 with some perfluoroalkenes result in compounds such as $(\text{CF}_3)_2\text{CFONF}_2$, $\text{F}_2\text{C}(\text{ONF}_2)_2$, and $\text{FOCF}_2\text{ONF}_2$. The compound $\text{FCO}(\text{ONF}_2)$ was synthesized reproducibly in good yields by the reaction of $(\text{FCOO})_2$, N_2F_4 , and small amounts of BF_3 [669, 670]. The compound $\text{F}_2\text{C}(\text{ONF}_2)_2$ had a boiling point of 264 K (-9°C), the vapor pressure described by

$$\log p \text{ (mm Hg)} = 8.075 - \frac{1374}{T} \text{ (K)},$$

and the density equation

$$d = 2.01 - 1.52 \times 10^{-3} T$$

The compound $\text{F}_2\text{COF}(\text{ONF}_2)$ had an estimated boiling point of 244 K (-29°C).

6.4.4 Toxic Properties of Trifluoramine Oxide

Trifluoramine oxide is very toxic. Experiments with albino rats showed that the LD50 concentration for 10-min exposure was between 200 and 500 ppm.

A specially built animal-exposure chamber was used for inhalation-toxicity studies with trifluoramine oxide [671]. The gas was introduced into the chamber through a calibrated micrometer valve. Specified ONF_3 concentrations were reached within

5 min after closure of the chamber and were monitored by a continuous IR scanning technique. The concentrations were stable and reproducible between 10 and 100 ppm.

Acute inhalation and intraperitoneal toxicities of ONF_3 were determined in rats and mice [672]. The LC_{50} values after exposing male rats or mice for 4 h (deaths within 7 days) were 24.2 and 17.5 ppm, respectively. The LC_{50} values after exposing male rats for 60, 30, or 15 min were between 87 and 104 ppm, between 119 and 149 ppm, and between 202 and 240 ppm, respectively. The intraperitoneal LD_{50} values for male rats or mice (deaths within 7 days) were 51.6 and 32.1 mg/kg, respectively. ONF_3 produced strong irritations resulting in pulmonary edema and hemorrhage after inhalation, as well as local denatured changes and accumulation of clear exudate after intraperitoneal injection. ONF_3 was quickly absorbed by rats after intraperitoneal injection. Fluoride increased quickly in the blood and concentrated in various tissues, especially thyroid, bone, and teeth. Most of the fluoride was excreted in urine, and a considerable amount was also recovered in feces.

The adverse effects of NF_3O on lower organisms have been examined [673]. The gas caused minimum damage to plants when they were exposed for 30 min to concentrations as low as 5 ppm. Effects on goldfish maintained in aquaria under 1% NF_3O for 30 min were negligible; salmon were moderately sensitive. Microorganisms in soil were only slightly decreased in numbers by 1 h of exposure, which was done by continuously tumbling soil particles through 1% NF_3O . Potentially useful decontamination reactions were studied. Interhalogens and N_2F_4 can probably be removed from the atmosphere by a mist of aqueous sodium bicarbonate solution. No reagent portable enough and sufficiently effective to remove OF_2 and NF_3O gas from the atmosphere was found. NF_3 is virtually non-reactive.

6.4.5 Applications of Trifluoramine Oxide

Although much of the synthesis work on nitrogen fluorides and nitrogen oxygen fluorides has been funded by U.S. government agencies interested in their use as rocket propellants, no rocket engine tests using trifluoramine as the oxidizer have yet been reported.

Other applications have been discussed, for instance as a replacement for nitrogen trifluoride in the cleaning of CVD equipment in the production of semiconductors. Nitrosyl fluoride FNO and trifluoramine oxide F_3NO were evaluated as candidates for new CVD chamber cleaning gases [674]. NF_3 and C_2F_6 , which have been used up to this time, were measured as the reference. FNO is highly susceptible to hydrolysis. F_3NO is expected to decompose more easily than NF_3 in the atmosphere because its N—F bond has been weakened by the introduction of an N=O bond into the molecule. Hence, the contribution to global warming of these compounds is expected to be small. Performance of these gases was evaluated by measuring their etch rates and their exhaust gases. The results showed that the etch rate of F_3NO was virtually the same as that of NF_3 , whereas the etch rate of FNO was about half that of NF_3 .

6.5 Nitrosodifluoroamine

The purple color of condensed tetrafluorohydrazine is often due to trace amounts of nitrosodifluoroamine (F_2NNO). It was estimated that as little as 0.1% NF_2NO in liquid N_2F_4 will give a pronounced purple color to the solution. When a mixture of tetrafluorohydrazine and nitric oxide was passed through a coil at elevated temperature (573 K [300 °C]) and then allowed to impinge upon a Pyrex cold finger at liquid nitrogen temperature, a dark purple deposit was formed [675].

In order to get maximum conversion of N_2F_4 into NF_2NO , it was necessary to use an excess of NO. If a sample of prepared NF_2NO is allowed to warm up to room temperature, the gases produced have the following composition (as determined by mass spectrometry): 65.0% NO, 32.4% N_2F_4 , and 1.8% N_2O . This is the composition that one would expect if NF_2NO decomposed according to the equation

This easy dissociation is in reversal of its formation.

Thermally unstable nitrosodifluoroamine can be synthesized from pyrolyzed N_2F_4 and an excess of NO in a cold trap that forms the inlet to a mass spectrometer, with analysis by mass spectrometry immediately after its formation [676]. Operating at low temperatures will also allow one to examine the sample for dimer association in the vapor phase. The appearance potential of NF_2^+ from NF_2NO was 12.12 eV.

Both *ab initio* methods and DFT methods have been applied to model geometries of F_2NNO , F_2NNO_2 , and their building components (NF_2 , NO, and NO_2) [677]. The geometries and energies of the structures were compared to experimental values when available.

The structure and energetics of several isomers of the nitrosamines have been investigated using quantum chemical calculations [678]. A comparison of the structure and stabilities of the H_2NNO and F_2NNO species resulted in the observation of both species possessing the same lowest energy isomer, i.e., the isomer with F_2NNO connectivity with C_1 symmetry.

Nitrous oxide, N_2O , was observed to react with F_2 under UV irradiation at 77 K (−196 °C) to initially form $\text{F}_2\text{N}_2\text{O}$, which, in accordance with earlier reports from the literature, decomposed above 133 K (−140 °C) to form N_2F_4 and NO [679]. A reaction mechanism for the formation and decomposition of F_2NNO from N_2O and F_2 and from N_2F_4 and NO has been suggested using valence bond theory considerations. The structure of F_2NNO was fully optimized at the electron-correlated level of theory and was shown to possess C_1 symmetry. A frequency analysis clearly showed the C_1 structure to represent a true energy minimum, whereas the earlier proposed planar C_s structure was shown to represent a first-order transition state. See also [18].

6.6 Nitrodifluoroamine

The highly unstable nitrodifluoroamine F_2NNO_2 is formed in the reaction of dissociated N_2F_4 with NO_2 at 583 K and rapid quenching at 77 K:

Nitrodifluoroamine O_2NNF_2 was prepared by passing N_2F_4 through a capillary furnace at 583 K (310 °C), mixing dissociated N_2F_4 ($\bullet NF_2$) with NO_2 at the capillary exit, and immediately quenching the product to 77 K (−196 °C) [680]. From mass spectral data, the appearance potentials for ONF, NO_2F , NO_3F , ONF_3 , $ONNF_2$, and O_2NNF_2 were determined, from which some thermodynamic quantities could be derived. The heats of formation of ONF, NO_2F , and $ONNF_2$ were lower than earlier values reported in the literature, suggesting possible excess energy in the ionization processes. The derived heats of formation of $ONNF_2$ and O_2NNF_2 gave N–N dissociation energies of $D(ON–NF_2) = 0.82$ eV and $D(O_2N–NF_2) = 0.71$ eV, respectively.

6.7 Fluorodinitroamine

NF_3 and $N(NO_2)_3$ are known compounds, whereas the mixed fluoronitroamine $FN(NO_2)_2$ had been unknown until 2014. Fluorodinitroamine, $FN(NO_2)_2$, was prepared by the fluorination of the dinitramide anion using NF_4^+ salts as the preferred fluorinating agent and was characterized by multi-nuclear NMR and Raman spectroscopy [681, 682]. Numerous experimental conditions for the synthesis of $FN(NO_2)_2$ have been investigated, including the use of $KN(NO_2)_2$ or $CsN(NO_2)_2$ as starting materials and NF_4SbF_6 , NF_4BF_4 , F_2 , or $FOSO_2F$ as fluorinating agents. The preferred combinations were $KN(NO_2)_2$ and NF_4SbF_6 in either SO_2 at 209 K (−64 °C) or CH_3CN at 243 K (−30 °C). $FN(NO_2)_2$ is a colorless solid at low temperatures and melts at about 179 K (−94 °C) to a colorless liquid. It is a thermally unstable, highly energetic material that decomposed above 253 K (−20 °C) to N_2O_4 , *trans*- N_2F_2 , N_2O , and FNO_2 . The ^{19}F NMR spectrum showed a single, somewhat broadened resonance at 53 ppm, which was in good agreement with those previously observed for the similar compounds F_2NNF_2 (60.4 ppm), $FN=C(CN)(CH_3)$ (60 ppm), and $FN=C(CF_3)_2$ (48.3 ppm).

7 Nitrogen Chloride Fluorides

Nitrogen trichloride is notoriously unstable and would not be considered as a rocket propellant. Nitrogen trifluoride is stable and has been considered as a rocket propellant. Intermediate compounds exist in the form of nitrogen dichloride fluoride and nitrogen chloride difluoride, which exhibit intermediate stability and are mostly of interest as intermediates in the synthesis of other fluorine compounds. Nobody would want to use them as rocket propellants. Chlorodifluoroamine (chlorodifluoroamine, nitrogen chloride difluoride, ClNF_2) is a gas that can be used as an intermediate in the synthesis of other difluoroamino compounds such as tetrafluorohydrazine.

7.1 Preparation of Chlorodifluoroamine

Chlorodifluoroamine, ClNF_2 , CAS RN [13637-87-1], has been prepared by reaction of difluoroamine with boron trichloride, phosgene, or hydrogen chloride [683]. It can also be obtained by treating a mixture of sodium azide and sodium chloride with elemental fluorine. Ammonia in the form of the simple salts NH_4F and NH_4HF_2 reacts under certain conditions with ClF_3 to yield chlorodifluoroamine, NF_2Cl . The reaction of difluoroamine with hydrogen chloride produced chlorodifluoroamine [684, 685]:

The Lawton patent also contains an IR spectrum of this compound.

The reaction of difluoroamine with chlorine gives chlorodifluoroamine [686]. The difluoroamine precursor can be prepared by hydrolysis of difluorourea or perfluorourea [381, 397, 399, 687]. The difluoroamine has a melting point of 157 K (-116°C), a boiling point of 249.5 K (-23.6°C), and a density of

$$\rho = 1.424 - 0.00202t$$

where ρ is the density in g/cm^3 and t is the temperature in degrees Celsius.

A more convenient synthesis is the reaction of difluoroamine with *tert*-butyl hypochlorite [688]. See also [689].

The chlorofluoroamines NFCl_2 and NF_2Cl were prepared by fluorination of an $\text{NH}_4\text{Cl}/\text{NaCl}$ mixture and characterized by vibrational spectroscopy [690]. For NF_2Cl , two fundamental vibrations had to be reassigned.

7.2 Physical Properties of Chlorodifluoroamine

Chlorodifluoroamine ClNF_2 is readily identified by three intense absorptions in its IR spectrum at 930, 854, and 697 cm^{-1} , corresponding to symmetric and asymmetric N—F stretching and N—Cl stretching, respectively [691].

7.3 Chemical Properties of Chlorodifluoroamine

The reaction of chlorodifluoroamine with mercury produces tetrafluorohydrazine. The reversal of this reaction is the reaction of tetrafluorohydrazine with chlorine, which results only in an equilibrium mixture of the two reactants and the product [692].

The photolysis of chlorodifluoroamine results in the formation of difluoroamino free radicals similar to those formed by photolysis of N_2F_4 [693, 694].

8 Fluoroamine and Difluoroamine

Fluoroamine and difluoroamine are too unstable to be used as rocket propellants, but they can serve as intermediates in the synthesis of more stable fluorides such as tetrafluorohydrazine.

8.1 Fluoroamine

Fluoroamine (monofluoroamine, fluoramine, FNH_2 , CAS RN [15861-05-9]) can be synthesized by vaporizing the adduct $NH_2F \cdot 2HF = NH_3F^+ HF_2^-$ in a dynamic vacuum. The reaction gas is passed through activated, powdered KF to absorb HF and is collected at 76 K [20]:

Above 173 K, fluoroamine decomposes:

As a weak base, fluoroamine reacts with strong acids, e.g., H_2F_2 , HSO_3F , $HClO_4$, or H_2SO_4 , forming fluorammonium salts $NH_3F^+ X^-$.

8.2 Difluoroamine

Difluoroamine (difluoramine, fluorimide, F_2NH , CAS RN [10405-27-3]) is extremely unstable and requires very careful handling because it often explodes spontaneously, especially on freezing or melting. A summary of the chemistry of difluoroamine is published in [695].

8.2.1 Preparation of Difluoroamine

Difluoroamine can be obtained by the hydrolysis of *N,N*-difluorourea with concentrated sulfuric acid [696]:

8.2.2 Physical Properties of Difluoroamine

Difluoroamine has a melting point of 156.6 K and a boiling point of 249.4 K. The boiling point is considerably higher than the boiling point of NF_3 (144.2 K) due to hydrogen bonding in the liquid, forming molecular clusters. *Ab initio* calculations have been performed on difluoroamine clusters consisting of up to four molecules [697]. The dimer, trimer, and tetramer were all found to exhibit two minima.

8.2.3 Chemical Properties of Difluoroamine

One of the primary properties of ammonia is that it is readily protonated to form ammonium ions. The question was whether substitution of one or two hydrogens in ammonia will change its basicity and the mobility of the remaining hydrogen in ion-exchange reactions. Isotope exchange is one method to determine the rates of protonation and deprotonation. It is known that increasing the acidity will accelerate the proton (deuteron) exchange in NH_3/ND_3 . Similar tests have been conducted with HNF_2 in D_2O [698, 699]. The exchange of hydrogen between HNF_2 and D_2O was first order with respect to HNF_2 and zero order with respect to D_2O , with an activation energy of $18.8 \text{ kJ/mol} = 4.5 \text{ kcal/mol}$.

Electrolytic reduction of HNF_2 in a four-electron process leads to ammonia. Attempts were made to protonate HNF_2 or F_3CNF_2 to see whether ammonium-type cations such as H_2NF_2^+ or $\text{F}_3\text{CNHF}_2^+$ were possible [700, 701]. Under a variety of protonation conditions, no evidence of salt formation could be found.

In another attempt to protonate HNF_2 , successive small increments of HCl were added to HNF_2 in a cold bath adjusted to 161, 146, and 135 K (−112, −127, and −138°C) [702, 703]. The two compounds were miscible over the entire range of compositions and temperatures, and no adduct formation could be detected. Using $\text{Al}(\text{CH}_3)_3$ as the Lewis acid resulted in explosions and/or methane formation.

IR and Raman spectra of HNF_2 and DNF_2 in the liquid and solid phases showed that the compounds are associated through hydrogen bridges between the nitrogen atoms [704]. Raman spectra of the KF , RbF , and CsF adducts and IR spectra of the RbF adduct of difluoroamine were interpreted in terms of strongly hydrogen-bridged anions [705]. Potassium, rubidium, and cesium fluoride crystals form complexes when HNF_2 is condensed onto them. When the potassium or rubidium complexes were allowed to warm to room temperature, they reacted further and formed *cis*- and *trans*-difluorodiazene and the alkali metal bifluorides. The cesium complex exploded before

reaching room temperature. The reaction of $\text{KF} \cdot \text{HNF}_2$ with OF_2 resulted in the formation of N_2F_4 .

Difluoramine is a weak base that can form adducts with Lewis acids (BF_3 , BCl_3 , PF_5 , SO_2) that are formed at 195 K and decompose well below ambient temperature. NHF_2 reacts with AsF_5 in anhydrous HF below 195 K to $\text{NH}_2\text{F}_2^+ \text{AsF}_6^-$. Otherwise, difluoramine reacts as an acid. The difluoroamide anion often reacts to form *cis/trans* N_2F_2 in the absence of other reaction partners. Ferric ion Fe^{3+} oxidizes NF_2^- to dinitrogen tetrafluoride N_2F_4 .

8.2.3.1 Decomposition of Difluoroamine

Anhydrous difluoroamine decomposes thermally (in the presence of KF as HF absorber) to dinitrogen difluoride

9 Other Nitrogen–Oxygen–Fluorine Compounds

Another stable polynitrogen ion, the second known example of a stable nitrogen fluoride oxide ion, $[\text{N}_3\text{NFO}]^+$, was prepared as its $[\text{SbF}_6]^-$ salt and characterized by multi-nuclear NMR and vibrational spectroscopy and electronic-structure calculations [706]. The cation is planar and exists as two stereoisomers.

Nitrogen Oxides

Coverage of nitrogen oxides had to be spread out over seven chapters because a single chapter on the topic would have been very large and would have made it more difficult for readers to find information on a specific compound. In addition, arranging 30 chapters among 5 subvolumes in such a way that each subvolume was about the same size represented a formidable challenge. A book with smaller chapters made our task easier.

The other six chapters in this series are titled “Nitrous Oxide,” “Nitric Oxide,” “Dinitrogen Trioxide,” “Nitrogen Dioxide,” “Dinitrogen Tetroxide,” and “Dinitrogen Pentoxide.”

Nitrogen commonly forms several different oxides with oxygen, depending on the state of oxidation of the central atom, nitrogen. The state of oxidation of nitrogen can be +1, +2, +3, +4, +5, or +6. The correct names of the six oxides are nitrous oxide, N_2O , nitric oxide, NO , dinitrogen trioxide, N_2O_3 , nitrogen dioxide, NO_2 , dinitrogen tetroxide, N_2O_4 , dinitrogen pentoxide, N_2O_5 , and nitrogen trioxide, NO_3 . Nitrogen dioxide, NO_2 , is used mostly in its dimeric form, dinitrogen tetroxide, N_2O_4 , which can be stored as a liquid at room temperature. The state of oxidation of nitrogen in dinitrogen tetroxide is the same as that in nitrogen dioxide. Because the valency of nitrogen in covalent bonds with oxygen is a maximum of four, the structure of dinitrogen pentoxide must be formulated with semipolar bonds, similar to those observed in nitric acid. Nitrogen trioxide, NO_3 , and its dimer N_2O_6 contain peroxide —O—O— linkages, but these compounds are unstable and occur only briefly as intermediates in reactions of other nitrogen oxides.

Nitrogen forms at least six covalently bound oxides, N_2O , NO , N_2O_3 , NO_2 , N_2O_5 , and NO_3 , which are all thermodynamically unstable with regard to their tendency to decompose to dinitrogen and dioxygen. Two of these oxides dimerize by way of $\pi^*-\pi^*$ interactions. Although all nitrogen oxides (in the gas phase) have positive enthalpies of formation, they still are not intrinsically unstable, with the exception of the paramagnetic radical $\bullet\text{NO}_3$, which has not yet been isolated as a pure substance.

As far as rocket propellants are concerned, the first two oxides in this family of nitrogen oxides, nitric oxide and nitrous oxide, have not found the same widespread application as dinitrogen tetroxide and its mixtures with dinitrogen trioxide or nitric acid. The last two oxides in this series, N_2O_5 and NO_3 , are thermally unstable and not suitable as rocket propellants.

During the past 15 years, nitrous oxide, N_2O , has found applications as an oxidizer in hybrid rocket engines, and this use is increasing. It can also be used as a monopropellant.

Oxygen is the third most abundant element in the Universe after hydrogen and helium. Wherever it is available in the presence of nitrogen and exposed to cosmic ra-

diation, one must assume that nitrogen oxides may form and condense in colder parts of the system. Therefore, nitrogen oxides are expected to be present in the solid phase in giant gas planets and “icy” grain mantles of comets and interplanetary particles. Being able to find condensed nitrogen oxides or nitric acid on any extraterrestrial body that might be a destination for future space travel would be a great bonus to In-Situ Resource Utilization (ISRU). The presence of perchlorate in the ice and soil on Mars has been a big surprise, and the occurrence of nitrates falls in the same category.

1 Nomenclature of Nitrogen Oxides

Dinitrogen tetroxide, N_2O_4 , often erroneously or negligently also called nitrogen tetroxide or nitrogen peroxide, and its mixtures with dinitrogen trioxide or nitric acid have found widespread applications as storable and hypergolic oxidizers and occupy the main portion of this chapter. Nitrogen tetroxide would be NO_4 , but this compound does not exist. Another erroneous designation for N_2O_4 is *nitrogen peroxide*, which was derived from the French name for the compound, *peroxyde d'azote*, but translated into English incorrectly. A common abbreviation for N_2O_4 is NTO, which is short for **d**initrogen **t**etroxide. This very popular abbreviation may partially be responsible for the frequently used misleading name *nitrogen tetroxide*. Nobody has proposed thus far to correct the situation by using the abbreviation DNTO for **d**initrogen **t**etroxide. It would be cumbersome to have to add the extra letter D. It would be easier to keep in mind that if the abbreviation NTO is used in this book or in any other rocket propellant literature, this actually stands for **d**initrogen **t**etroxide and the D was dropped as a matter of convenience.

Because the other nitrogen tetroxides, NO_4 and N_3O_4 , do not exist as neutral molecules or are only short-lived, there is very little chance that the name *nitrogen tetroxide* used for N_2O_4 will get confused with other nitrogen tetroxides. NO_4 exists in the form of the short-lived peroxyxynitrate ion NO_4^- , which plays an important role in atmospheric pollution (smog) chemistry. N_3O_4 exists in the form of dinitramide ion N_3O_4^- , which is relatively stable and is present in ammonium dinitramide (ADN), a new rocket propellant ingredient.

There is only a slight possibility of confusion because the common abbreviation (acronym) for 3-**n**itro-1,2,4-**t**riazol-5-**o**ne, a solid energetic material widely used as explosive and propellant additive, is also NTO. However, one can usually guess from the context in which the abbreviation NTO is used whether the author means the liquid oxidizer NTO or the solid explosive NTO.

Dinitrogen pentoxide, N_2O_5 , and nitrogen trioxide, NO_3 , are unstable and unsuitable as rocket propellants. Dinitrogen pentoxide is an active nitrating agent for the synthesis of organic nitro compounds used as energetic materials.

2 Physical Properties of Nitrogen Oxides

The densities and molecular volumina of nitrogen oxides in the frozen state were measured at low temperatures [1]. Table 1 gives a comparison and summary of the most important physical properties of nitrogen oxides.

Table 1: Comparison and summary of physical properties of nitrogen oxides.

Compound name	Chemical formula	Melting point		Boiling point		Oxygen content	Molecular mass g/mol
		K	°C	K	°C	Mass-% O	
Nitrous oxide	N ₂ O	170.7	−102.4	183.6	−89.5	36.35	44.016
Nitric oxide	NO	110	−163	121.3	−151.8	53.32	30.008
Dinitrogen trioxide	N ₂ O ₃	171	−102	—	—	63.14	76.016
Dinitrogen tetroxide (nitrogen dioxide)	N ₂ O ₄ (⇌2NO ₂)	261.9	−11.2	294.3	+21.15	69.55	92.016
Dinitrogen pentoxide	N ₂ O ₅	—	—	Sublimes at 307.1	Sublimes at +34 °C	74.06	108.016
Nitrogen trioxide	NO ₃ (⇌ 1/2 N ₂ O ₆)	131 (dec.)	−142 (dec.)	—	—	77.41	62.008

2.1 Optical Properties and Spectra of Nitrogen Oxides

The spectral properties of nitrogen oxides provide information about the molecular structure of the molecules and excited states they go through as they decompose. Spectra are also used to identify short-lived intermediates of decomposition reactions. Spectroscopy is the main tool in the search for oxides with higher oxidation states of nitrogen or nitrogen oxides formed in complex ring structures that might be useful as more energetic oxidizers in rockets. Most of the spectroscopic work on nitrogen oxides found in the literature deals with the mechanisms of formation, destruction, and identification of nitrogen oxides in the atmosphere, where they are notorious as atmospheric pollutants but also serves a vital mechanism for abiotic nitrogen fixation that provides much needed nitrogen fertilizer nutrients for all growing plants.

2.2 Infrared Absorption Spectra of Nitrogen Oxides

In what follows there are several sections describing the IR spectra of individual nitrogen oxides. Here we provide links to some overview studies that investigate more than one nitrogen oxide at a time, dealing with several as a group and comparing them. The same papers may be referenced again in later sections on specific nitrogen oxides.

A nice summary of IR and Raman spectra of all nitrogen oxides, including their ions, is contained in [2]. IR studies have been made of several oxides of nitrogen trapped at liquid-helium temperatures in matrices of Ar, N₂, O₂, CO₂, H₂, or N₂O [3]. NO was found as the monomer and two forms of dimer, *cis* and *trans*. The *cis* is more stable than the *trans* isomer. NO₂ was found as the monomer, the known stable dimer of planar structure, and two new dimers. One of these has the ONO–NO₂ structure, and the other may be the twisted V_d form of the stable dimer. N₂O₃ was found in its stable form ON–NO₂ and in a second form whose spectrum was consistent with the structure ONONO. Observations on covalent N₂O₅ were also reported.

2.3 Thermodynamic Properties of Nitrogen Oxides

Exact knowledge of the thermodynamic properties of nitrogen oxides is required to calculate theoretical rocket performance and evaluate reactions among the nitrous oxides themselves, including dissociations and (re)combination reactions.

The ideal gas chemical thermodynamic properties for NO, NO₂, N₂O₃, and N₂O₄ for the temperature range 50 to 5000 K were evaluated by a statistical thermodynamic method using the most recent molecular parameters [4]. In the calculations for NO and NO₂, the effects of anharmonicity and vibration-rotation interaction were included. The contributions due to centrifugal distortion were also included for NO₂. For evaluation of the thermodynamic properties for N₂O₃ and N₂O₄ molecules, the rigid-rotor and harmonic-oscillator models were adopted. A free internal rotation was assumed for N₂O₃ and an internal rotation barrier height (V₂) of 6.61 kJ/mol (1.58 kcal/mol) was assumed for N₂O₄. The thermodynamic properties due to hindered internal rotation were calculated using a partition function formed by summation of internal rotation energy levels. The thermodynamic properties for two equilibrium mixtures, NO₂ ⇌ N₂O₄ and N₂O₃/NO/NO₂/N₂O₄, were also calculated. The effects of temperature and pressure on heat capacities and compositions of these two mixtures were illustrated graphically, and the calculated heat capacities and equilibrium constants were in good agreement with available experimental values.

2.4 Molecular Structure of Less Common Nitrogen Oxides

The various chapters of this book contain several sections describing the molecular structure of individual nitrogen oxides. Here we summarize some overview studies that investigate more than one nitrogen oxide at a time, dealing with several as a group. We also discuss some of the less common nitrogen oxides, some of which are only hypothetical and exist only on paper (or on screen).

The nitrogen oxides N_2O_2 , N_2O_3 , and N_2O_4 have many peculiar features: very long, weak N—N bonds, 2.18, 1.864, and 1.782 Å, with low heats of dissociation 11.3, 39.7, and 53.1 kJ/mol (2.7, 9.5, and 12.7 kcal/mol); a typical N—N single bond length is 1.47 Å, for instance, in hydrazine with a heat of dissociation of 19.7 kJ/mol (4.71 kcal/mol). The molecules are planar, although the O—O repulsions are at a maximum for this configuration. The barrier to internal rotation about the N—N axis is higher than would be expected for such long bonds, being 2.9 kcal/mol for N_2O_4 . The dinitrogen oxides are diamagnetic, whereas the building units, NO_2 and NO , are paramagnetic. The $\angle ONO$ bond angles in N_2O_3 and N_2O_4 are unusually large, being 129.8 and 135.4°. The nitroso $\angle NNO$ angles in N_2O_2 , 101.3°, and N_2O_3 , 105.1°, are smaller than in other NO compounds. N_2O_2 , N_2O_3 , and N_2O_4 have only nitrogen-nitrogen σ bonds weakened by oxygen lone-pair delocalization and no N—N π bonding.

One can speculate about the existence of nitrogen oxides that would promise higher performance as rocket propellants, but they have not yet been discovered, and if their existence can be proven, they exist only as short-lived intermediates during the formation or decomposition of other nitrogen oxides or they have to be trapped in a matrix of frozen inert gases. In most instances they can only be isolated and analyzed in a frozen matrix at very low temperatures. It would be possible to use them as cryogenic solid rocket propellants. Examples of this speculative group of nitrogen oxides are as follows:

Oxygen azide $N \equiv N = N - O - N = N \equiv N$

Equilibrium geometries, bond dissociation energies, dipole moments, harmonic vibrational frequencies, and IR intensities were calculated for a set of 10 neutral nitrogen oxides (NO , NO_2 , NO_3 , N_2O , *sym*- N_2O_2 , *asym*- N_2O_3 , *sym*- N_2O_3 , *sym*- N_2O_4 , *asym*- N_2O_4 , and N_2O_5) by applying one local and two gradient-corrected non-local functionals in a Gaussian-type-orbital density functional theory method [5]. Comparison with available experimental data showed that, except for the bond dissociation energies,

the local functional gave very accurate molecular properties. Non-local functionals considerably improved the bond dissociation energies, but the results still overestimated the experimental values by about 10 kcal/mol on average. For the other properties, the results obtained with non-local functionals were not necessarily superior to those calculated with the local functional. The properties of two molecules (*sym*-N₂O₃ and *asym*-N₂O₄) were predicted for the first time, and several reassignments were proposed for absorption bands in the vibrational spectra of dinitrogen oxides.

The simple molecule N₂O₄ might exist not only with N—N linkages, but also with O—O linkages. One of the speculative possible structures is

CAS RN [172300-39-9]

Nitroperoxious acid, OO-nitroso ester

Dinitroso peroxide

but it has not been identified as being coexistent with O₂N—NO₂. ONOONO is a short-lived red substance produced by autoxidation of NO with O₂ at 113 K in inert solvents. The red compound was diamagnetic and absorbed light maximally at 500 nm. The ONOONO intermediate was unstable above the melting point of 2-methylbutane, which was used as the matrix, and rapidly converted to O₂NNO₂. This peroxide is related to peroxyntitric acid, HOONO₂, and peroxyntitrous acid, HOONO. Its structure has been calculated using molecular orbital theory.

Six of the nine fundamental vibrational modes for *cis*, *cis*-HOONO, were assigned definitively and one tentatively to the IR absorption spectra of matrix-isolated *cis*, *cis*-peroxyntitrous acid (HOONO), and its deuterated isotopomer DOONO in Ar [6]. Results from coupled-cluster, *ab initio* anharmonic force field calculations helped to confirm some of the assignments.

The rotational spectrum of *cis-cis* HOONO was studied over a broad range of frequencies, 13–840 GHz, using pulsed beam Fourier transform microwave spectroscopy and submillimeter spectroscopy [7]. The inertial defects of HOONO and DOONO were consistent with a planar equilibrium structure with significant out-of-plane H atom torsional motion.

ONOO• is an important intermediate in the autoxidation of nitrogen monoxide by dioxygen. A red isomer of N₂O₄, ONOONO, formed in a matrix at 113 K from nitrogen monoxide and dioxygen, was converted to O₂NNO₂ upon warming. Two intermediates in the autoxidation of NO have been identified: **(1)** ONOO•, which was detected and identified by electron paramagnetic resonance (EPR) spectroscopy at 295 K and atmospheric pressure in the gas phase, and **(2)** ONOONO, a red substance produced at 113 K in a matrix [8]. The rate constant for formation in aqueous solution was higher than that in the gas phase, and, therefore, the half-life of ONOO• is longer in solution.

Pure *sym*-N₂O₄ isolated in solid Ne was obtained by passing cold neon gas over solid N₂O₄ at 158 K (–115 °C) and quenching the resulting gaseous mixture at 6.3 K [9]. Filtered UV irradiation (260–400 nm) converted *sym*-N₂O₄ into *trans*-ONONO₂, a weakly interacting (NO₂)₂ radical pair, and traces of the *cis*-N₂O₂•O₂ complex. Besides the weakly bound ON•O₂ complex, *cis*-N₂O₂•O₂ was also obtained by codeposition of NO and O₂ in solid Ne at 6.3 K, and both complexes were characterized by their matrix IR spectra. The IR spectra of *sym*-N₂O₄ and of *trans*-ONONO₂ in solid Ne were recorded. IR fundamentals of *trans*-ONONO₂ were assigned based on experimental ¹⁶O/¹⁸O isotopic shifts and guided by Density Functional Theory (DFT) calculations. Dinitroso peroxide, ONOONO, a proposed intermediate in the IR photoinduced rearrangement of *cis*-N₂O₂•O₂ to the various N₂O₄ species, was not detected. Its absence in the photolysis products indicated a low barrier (≤10 kJ/mol) for its exothermic O–O bond homolysis into a (NO₂)₂ radical pair.

It has been common practice in the rocket propulsion community to call N₂O₄ *nitrogen tetroxide*, omitting the prefix *di*-, which is chemically incorrect because *nitrogen tetroxide* would refer to the non-existent NO₄. Speculation has it that NO₄, if it existed, could have one of the following molecular structures, most of which have been characterized by computational chemistry, but none of them proved to be stable enough for use as a rocket propellant:

NO₄

1,2,4,5-Tetraoxa-3-azoniaspiro[2.2]pentane
CAS RN [204273-63-2]

NO₄

Dioxaziridinyldioxy
CAS RN [193016-83-0]

NO₄

Tetroxazolidinyl
CAS RN [193016-71-6]

NO_4 exists in the form of the peroxyxynitrate ion NO_4^- (CAS RN [125239-87-4]), whose parent, peroxyxynitric acid, plays an important role in atmospheric air pollution (smog) chemistry. Organic peroxyxynitrates are thermally unstable intermediates (at ambient temperatures) in the atmospheric degradation of hydrocarbons.

2.4.1 Computational Chemistry of Nitrogen Oxides

In many cases, properties of nitrogen oxides that have not yet been identified as existing in the laboratory but have been envisioned by theoretical chemists have been calculated by computational chemistry. This includes nitrogen oxides that exist as short-lived intermediates in the reactions between nitrogen and oxygen or among other nitrogen oxides, and nitrogen oxides of higher states of oxidation of nitrogen that were speculated to make good oxidizers (better than N_2O_4) in rocket propellants.

Self-consistent molecular orbital (MO) bond orders for a number of the simpler nitrogen-oxygen compounds were calculated and attempts made to correlate bond lengths and force constants with bond orders for these molecules [10].

Ab initio computational methods were used to obtain $\Delta_r H^\circ$, $\Delta_r G^\circ$, and $\Delta_r S^\circ$ for the reactions

at 298 K [11]. The standard entropies were compared with values cited in the NIST/JANAF tables. With the exception of reaction I, in which the dimer is weakly bound, and reaction V, for which thermodynamic data appear to be lacking, the calculated standard thermodynamic functions of reaction were in good agreement with literature values obtained both from statistical mechanical and various equilibrium methods. The potential surface for the dissociation of N_2O_4 was explored using multi-reference methods. No evidence of a barrier to dissociation was found.

2.5 Chemical Reactions of Nitrogen Oxides

All nitrogen oxides are quite reactive and undergo a multitude of reaction types with other chemicals. A good summary of reactions of nitrogen oxides was published in 1972 [12].

The following schematic illustrates the many interconversion reactions taking place among the several nitrogen oxides [2]:

Laane, J., and J. R. Ohlsen, Characterization of nitrogen oxides

2.6 Summary Literature on Nitrogen Oxides

Since nitrogen oxides have been known for a long time, and because they occupy an important place among industrial chemicals and atmospheric pollutants, a large body of literature exists on the chemistry of nitrogen oxides, but only a fraction of that deals with nitrogen oxides as rocket propellants. We try to fill this gap. Here we give a list of summary and review publications on nitrogen oxides. Most of these deal mainly with dinitrogen tetroxide, but others are covered as well. Most chemical handbooks and encyclopedias have chapters on nitrogen oxides, such as Kirk-Othmer, Ullmann's, or Fedoroff. Other surveys are available in the periodical and report literature [13]. Entire conferences have been devoted to dinitrogen tetroxide and red fuming nitric acid (RFNA).

3 Nitric Oxide

The information on nitric oxide, NO, is in a separate chapter, “Nitric Oxide,” in *Encyclopedia of Oxidizers*.

4 Dinitrogen Trioxide

The information on dinitrogen trioxide, N₂O₃, is in a separate chapter, “Dinitrogen Trioxide,” in *Encyclopedia of Oxidizers*.

5 Nitrogen Dioxide

The information on nitrogen dioxide, NO_2 , is in a separate chapter, “Nitrogen Dioxide,” in *Encyclopedia of Oxidizers*.

6 Dinitrogen Tetroxide

The information on dinitrogen tetroxide, N_2O_4 , is in a separate chapter, “Dinitrogen Tetroxide,” in *Encyclopedia of Oxidizers*.

7 Dinitrogen Pentoxide

The information on dinitrogen pentoxide, N_2O_5 , is in a separate chapter, “Dinitrogen Pentoxide,” in *Encyclopedia of Oxidizers*.

8 Nitrogen Trioxide

The chemistry of nitrogen trioxide has not received much attention from researchers. For quite some time, chemists were not even sure whether this compound existed in its monomeric form, NO_3 , or whether it always occurred in a dimeric form N_2O_6 :

It is known to exist as a free radical, $\bullet\text{NO}_3$. Nitrogen trioxide is said to be formed by the reaction of dinitrogen pentoxide and ozone or by electric discharges in oxygen-nitrogen mixtures. Nitrogen trioxide forms colorless crystals that readily decompose into dinitrogen pentoxide and oxygen. So far, it has not been possible to make solid or liquid nitrogen trioxide in the pure state because it is difficult to separate from ozone. It has been suspected that nitrogen trioxide exists only in equilibrium mixtures with dinitrogen pentoxide and ozone. It has also been suspected that it is a short-lived intermediate during the combustion of rocket propellants where it was observed by mass spectrometry [14].

9 Other Nitrogen-Oxygen Compounds

With a little imagination and trying to build ring, polycyclic, or even caged structures patterned after known hydrocarbon or heterocyclic structures, one can imagine other exotic nitrogen oxides that might turn out to be rocket propellant oxidizers potentially

better than dinitrogen tetroxide. Speculation about the existence of higher oxides of nitrogen (higher than N^{+5}) started early [15]. Before actually attempting to synthesize them in the lab, computational chemistry nowadays has enabled theoretical (theoretician) propellant chemists to predict the thermal stability and enthalpy of formation of many of those postulated N_xO_y compounds. Consequently, there are quite a few publications in the literature dealing with purely speculative, imaginative molecules in which many nitrogen and oxygen atoms are linked to form a molecule with a high energy and high oxygen content. Several of these speculative nitrogen oxides were already discussed in the introductory section to nitrogen oxides in the chapter on nitrogen oxides.

Previous studies of open-chain metastable polymers of the nitrogen oxides were extended to polycyclic $(ONNO)_x$ compounds [16]. SCF MO AM1 calculations indicated that such polymers would be comparable in thermodynamic and kinetic stability to the open-chain isomers. Results for the parent molecule, a cyclic dimer of N_2O , and for oligomers ≤ 7 rings in length, and a comparison of neat oligomers and oligomers in which the terminal *cis* azo groups are hydrogenated showed that the favored conformer would be a series of boats. Activation enthalpies for homolytic cleavage of N—N and N—O bonds in three model compounds were on the order of 42–83 kJ/mol (10–20 kcal/mol). Realization of the polymer would be expected to require extreme pressures, in which case the existence of the known *cis*-ONNO in the solid state would probably result in the formation of polycyclic material by the concerted polymerization of the dimer rather than by way of fusion of two open-chain $(NONO)_x$ molecules.

Planar N_x systems, such as $\text{cyclo-}N_5^-$ and N_5^+ , tend to be more stable than nonplanar systems, such as the neutral $\text{cyclo-}N_6$. It has been proposed that the key to stabilization is the separation of the σ and π electron systems [17]. In both $\text{cyclo-}N_5^-$ and N_5^+ , a six- π -electron system is created upon either adding to or removing from the $\text{cyclo-}N_5$ radical one electron. It was speculated that judicious addition of oxygen atoms to polynitrogen ring compounds such as $\text{cyclo-}N_4$ and $\text{cyclo-}N_6$ can increase their thermodynamic and kinetic stabilities, accompanied by only a small loss in their efficiency as high energy density materials, actually improving their utility as oxidizers. The properties of some of these compounds were calculated and compared with the parent all-nitrogen compounds. Coordination of one or more oxygen atoms to the ring leads to effective separation of the σ and π electron systems helping to stabilize the systems. The exocyclic N—O bonds can assume a single- or double-bond character, depending on the ring system.

Some of the nitrogen-oxygen compounds discussed here are closely related to the polynitrogens. The long sought after N_6 hexaazo-benzene ring that is isoelectronic with benzene can be stabilized by adding coordinate-covalent bonds from oxygen. Optimized structures, normal IR harmonic frequencies, heats of formation, and activation energies for unimolecular dissociation were calculated for the N_4O , N_4O_2 , N_6O , N_6O_2 , and N_6O_3 systems with oxygen atoms in the ring or attached to the ring [18]. By increasing the number of oxygen atoms adjacent to the ring, a nitrogen ring with

alternating positive and negative atomic charges can be created. In fact, the N_4O_2 , dioxatetrazine,

and N_6O_3 systems have completely planar structures and computed heats of formation of 523 and 647 kJ/mol (125.0 and 154.7 kcal/mol), respectively. Furthermore, these systems appear kinetically stable with barriers to unimolecular dissociation of 187 and 261 kJ/mol (44.8 and 62.4 kcal/mol), respectively. A boat-shaped conformation (C_{2v} structure) was determined to be a minimum equilibrium structure [19].

Various all-nitrogen molecules have been examined as candidates for high-energy-density materials (HEDMs) because of the energy release that would accompany the dissociation of such a molecule down to N_2 molecules. Numerous N_x molecules have been shown to dissociate too easily to be viable HEDMs, including small N_x all-nitrogen cages. One possible solution to the instability of small N_x cages is oxygen insertion into the N—N bonds. Conversion of N—N bonds into N—O—N bonding groups would relieve much of the ring strain in small N_x cages, thereby stabilizing the molecule and possibly making the N_xO_y molecule a good HEDM. If octaazacubane, N_8 , could be stabilized by attaching oxygen atoms or by changing N—N bonds to N—O—N bridges, that would be a very high energy high-density material. Several cage isomers of N_8O_4 were examined by theoretical calculations to evaluate their suitability as potential HEDMs [20]. Calculations are carried out with Hartree-Fock theory and Møller-Plesset perturbation theory (MP3 and MP4) to obtain the energy released if the molecule decomposes.

A purely speculative compound that has never been synthesized but would make a good rocket propellant is 1,3,5-trioxa-2,4,6-triazine $H_3N_3O_3$. The enthalpies of formation of the gas-phase species were computed according to the atomization energy method and gave $\Delta H_f^\circ(G) = +100.6$ kcal/mol [21]. The enthalpy of sublimation for $H_3N_3O_3$ was estimated as 74 kJ/mol = 17.7 kcal/mol according to Trouton's rule. With the estimated sublimation enthalpy, the enthalpy of formation for solid 1,3,5-trioxa-2,4,6-triazine was calculated to be $\Delta H_f^\circ(S) = +347$ kJ/mol = +82.9 kcal/mol. The density of $H_3N_3O_3$ was calculated to be $\rho = 1.60$ g/cm³ from the molecular volume.

9.1 Trinitroamide N_4O_6

Trinitroamide, trinitramide, N_4O_6 , $N(NO_2)_3$, trinitramine, trinitroamine, constitutes a possible energetic green oxidizer that could be suitable for future high-perfor-

mance rocket propellants. The structure of the molecule has jokingly been called a “propeller” molecule (Figure 1).

Figure 1: Molecular structure of trinitroamide.

Only a few speculative, theoretical works had predicted this nitrogen oxide until its existence was confirmed experimentally. The heat of formation ΔH_f° (gas) of trinitroamide had been estimated at between +159 and +297 kJ/mol (+38 and +71 kcal/mol), and the N–N bond dissociation energy had been estimated to be 83.7–113 kJ/mol (20–27 kcal/mol) [22].

Ab initio calculations predicted a stable C_3 structure for trinitroamide with N–N bond lengths of 1.545 Å and an enthalpy of formation of +247 kJ/mol (+59 kcal/mol) [23]. Thermal decomposition of trinitroamide most likely would occur via N–N bond cleavage, which would require about 109 kJ/mol (26 kcal/mol).

Results of *ab initio* calculations of the structures and energies of the mono-, di-, and trinitrosamides were compared to mono-, di-, and trinitroamides [24]. Accurate standard heats of formation of this series of nitroamides and nitrosamides were calculated using isodesmic reactions and high-level theories. The nitrosamides were predicted to have heats of formation at 0 K that were 83–166 kJ/mol (20–40 kcal/mol) higher than the analogous nitroamides. The N–N bond strengths were comparable whether a NO or NO₂ group was bonded to the central nitrogen atom. The data suggested that converting the nitro groups to nitroso groups might result in compounds with lower molecular weights, shorter N–N bond lengths, and higher energy content, at the expense of lower oxygen balance. It was suggested that nitrosamides are potentially useful high-energy materials. Using the same computational method, the revised ΔH_f° for NH₂NO₂ was predicted to be 3.8 kcal/mol at 0 K, in close agreement with previous theory, but very different from experiment. Predicted values for ΔH_f° were 142 and 297 kJ/mol (34 and 71 kcal/mol) for di- and trinitramide, respectively, and 92, 272, and 469 kJ/mol (22, 65, and 112 kcal/mol) for mono-, di- and trinitrosamide, respectively. Nitrosamides have bond strengths comparable to those of the nitramides.

The largest nitrogen oxide to date, trinitroamide, has been prepared following extensive quantum chemical studies in which its kinetic stability and several physical properties were estimated. Trinitroamide was finally detected using IR and nuclear

magnetic resonance (NMR) spectroscopy [25]. The compound is highly energetic and shows promise for cryogenic propulsion and as a reagent in HEDM research.

9.2 Nitrogen Tetroxide Cation NO_4^+

The structure and energy of the bicyclic nitrogen tetroxide cation, $\text{D}_{2d}\text{NO}_4^+$, and its C_{2v} transition state for dissociation into NO_2^+ and O_2 have been studied theoretically by the coupled-cluster and similarity-transformed equation-of-motion coupled-cluster methods [26, 27]. The computed energy of decomposition was 573 kJ/mol (137 kcal/mol). The gas-phase heat of formation was predicted to be +1548 kJ/mol (+370 kcal/mol). Nevertheless, its low dissociation barrier (50–71 kJ/mol = 12–17 kcal/mol) and high vertical electron affinity (8.4 eV) indicated that NO_4^+ will have a low stability, which will complicate its experimental observation.

9.3 Azido Oxide N_3O

The short-lived nitrogen-rich azido oxide N_3O has been detected in the gas phase by mass spectrometric experiments [28, 29]. The radical has been assigned a minimum lifetime of 0.7 μs , and an open-chain NNNO structure in the quartet state. N_3O^+ ions prepared in the source of a mass spectrometer under low-pressure conditions were submitted to neutralization by collisional electron transfer, leading to the observation of the novel neutral N_3O oxide:

In support of these experiments, the structures and energies of the N_3O^+ precursor ion and the N_3O radical have been calculated by *ab initio* methods. These compounds are too unstable to be used as rocket propellants.

9.4 Heptanitrogen Oxide Cation N_7O^+

The reaction of $\text{NOF}_2^+\text{SbF}_6^-$ with an equimolar amount of HN_3 in anhydrous HF at 228 K (−45 °C) produced $\text{N}_3\text{NOF}^+\text{SbF}_6^-$. When an excess of HN_3 was used, a new compound, $\text{N}_7\text{O}^+\text{SbF}_6^-$, was formed [30]:

However, this compound could not be isolated as a solid and rapidly decomposed in a quantitative manner with N_2O evolution to $\text{N}_5^+\text{SbF}_6^-$. This reaction represents a novel and more convenient synthesis for $\text{N}_5^+\text{SbF}_6^-$ because $\text{NOF}_2^+\text{SbF}_6^-$ is more readily accessible than $\text{N}_2\text{F}^+\text{SbF}_6^-$ and the N_5^+ can be labeled in all five positions with ^{15}N by the simple use of terminally singly labeled N_3^- . The formation of the N_7O^+ cation was established by isotopic labeling experiments and theoretical calculations. It was shown that the addition of a second azido ligand to the same central atom allows for an attack of the negatively charged N_α atom of one ligand by the positively charged N_γ atom of the second ligand, thereby greatly lowering the activation energy barrier toward decomposition and explaining why geminal diazides are much less stable than either monoazides or vicinal diazides.

9.5 Nitrosyl Azide NON_3

Nitrosyl azide, nitroso azide, N_4O , NON_3 , is a compound in the group of covalent (as opposed to ionic) azides. The characterization and usage of the covalent non-metal azides have obviously been hampered by their thermodynamic and kinetic instability. NON_3 , HN_3 , and all of the halogen azides are very hazardous. Especially dangerous are the pure halogen azides in the condensed phase. Violent explosions can also occur in the gaseous state upon sudden variations of the pressure.

It was found through a combined quantum chemical and experimentally observed study of gas-phase IR decomposition products that *trans-trans*- N_4O decomposed via rotation into the *cis-cis* isomer and cyclic N_4O to yield $\text{N}_2\text{O}(\text{C}_{\infty\text{v}})$ and N_2 . The unimolecular decomposition of nitrosyl azide (tetranitrogen monoxide), N_4O , was modeled by computer programs at the electron-correlated, spin-restricted RMP2 level [31–34]. It was demonstrated that the experimentally established *trans-trans*- N_4O (C_s) may either interconvert into *cis-cis*- N_4O , which upon decomposition forms cyclic $\text{N}_4\text{O}(\text{C}_{2\text{v}})$ as an intermediate species to finally give $\text{N}_2\text{O}(\text{C}_{\infty\text{v}})$ and N_2 , or *trans-trans*- N_4O may directly dissociate into cyclic $\text{N}_2\text{O}(\text{C}_{2\text{v}})$ and N_2 . All structures determined were rationalized by energy hypersurface calculations.

Motivated by the isolation and spectroscopic characterization of nitrosyl azide (N_4O), several *ab initio* investigations and valence-bond calculations of the originally reported structure, as well as various hypothetical structural isomers on the potential energy hypersurface, were undertaken [35]. Speculation was also extended to the mode of decomposition of nitryl azide, N_3NO_2 . Geometries and harmonic vibrational frequencies were predicted for the *trans*-chain isomer along with the 6- π electron po-

tentially aromatic ring structure with various levels of theory giving estimates for bond lengths and bond angles for the *trans*-chain and ring isomers. While the ring isomer was predicted to be the most stable structure on the hypersurface, the barrier to dissociation was very low, between 1 and 2 kcal/mol, making isolation theoretically possible but experimentally difficult. This small barrier also detracts from the attractiveness of the N_4O ring structure as a High Energy Density Material (HEDM). The *trans*-chain isomer, however, was found to lie in an energy valley with higher sides, consistent with previous experimental observations. High-level *ab initio* techniques have been used to aid experimentalists in discovering and characterizing new energetic molecules [36]. Methods used ranged from the self-consistent field approximation through DFT to coupled clusters with inclusion of single and double excitations. Characterization of minima and transition states between minima of nitrosyl azide surface revealed that the ring isomer is a poor high-energy-density candidate due to a low barrier to dissociation.

The formation of a new binary isomer of N_2O through the reaction of NS^+ salts with the azide anion was deemed highly unlikely. Therefore, the ongoing quest for cyclic N_2O continued due to the observation of *trans-cis* isomerization of the N_4O moiety [37].

Lucien may have obtained some nitrosyl azide, but in those early days he lacked the instrumentation to unambiguously identify it as a new compound and concluded only from the composition of the decomposition products (N_2O and N_2) that at one point he may have had nitrosyl azide in pure form [38].

Reaction products of the reaction of activated, anhydrous sodium azide with nitrosyl chloride were sublimed under vacuum at low temperature and gave a pale yellow condensate of N_4O [39].

The conformational and structural stability of nitrosyl azide $NNN-N=O$ and nitryl azide $NNN-NO_2$ were investigated by DFT and *ab initio* MP2 calculations [40]. Nitrosyl azide was predicted to exist predominantly in the planar *trans* (the angled NNN and $N=O$ groups are *trans* to each other) structure with a high *trans-cis* rotational barrier of about 46 kJ/mol (11 kcal/mol) as a result of pronounced conjugation between the azide group and the $N=O$ bond. The vibrational frequencies were calculated and the IR and Raman spectra plotted. Complete vibrational assignments were made on the basis of normal coordinate calculations for the stable conformers. For nitrosyl azide, the calculated wave numbers were compared to experimental values obtained from earlier reported Raman spectra of the molecule.

9.6 Nitryl Azide NO_2N_3

In addition to the well-characterized dimer of nitrous oxide (N_2O)₂, an isomeric nitrogen oxide with the gross formula N_4O_2 exists (at least on paper) as nitryl azide (nitroxyl azide, nitronium azide, nitro azide, NO_2N_3) CAS RN [40006-84-6]:

Azide salts, such as the alkali metal salts, react with nitronium salts to form nitryl azide, NO_2N_3 , whose existence was supported by IR and mass spectral data [41], but that observation could not be confirmed subsequently. Nitryl azide was supposed to be relatively stable at temperatures below 263 K (-10°C), but above 273 K (0°C) it decomposed quantitatively to N_2O . The formation of N_2O from N_4O_2 was at one time said to proceed via oxatetrazole-2-oxide as an intermediate.

The reaction behavior of NaN_3 , AgN_3 , and Me_3SiN_3 toward FNO_2 , ClNO_2 , NO_2SbF_6 , and NO_2BF_4 was investigated in search of nitryl azide and similar energetic nitrogen-oxygen compounds [42]. At 243 K (-30°C) or below in a solvent-free system, sodium azide did not react with ClNO_2 , NO_2BF_4 , or NO_2SbF_6 . Below 243 K (-30°C) silver azide did not react with neat ClNO_2 . Pure chlorine azide was isolated by fractional condensation and identified by its low-temperature Raman spectrum (liquid state). Treatment of FNO_2 with NaN_3 at temperatures as low as 195 K (-78°) always ended in an explosion, which was probably due to the formation of FN_3 as one of the reaction products. The reaction of NO_2SbF_6 with NaN_3 in liquid CO_2 ($-55 \leq T \leq -35^\circ\text{C}$) as the solvent afforded a new azide species that was stable at low temperatures in solution only and was investigated by means of low-temperature Raman spectroscopy. The vibrational data gave strong evidence for the presence of a tetranitrogen dioxide, N_4O_2 , which can be regarded as nitryl azide (NO_2N_3). The structure and vibrational frequencies of N_4O_2 were computed by an *ab initio* method.

Five N_4O_2 isomers and their possible decomposition pathways were investigated with Møller-Plesset perturbation theory (MP2) and DFT [43]. The most stable isomer was predicted to be the open-chain C_{2v} structure, which has not been reported previously. For all five N_4O_2 isomers, dissociation energies and eight transition states were studied. The open-chain isomer and the planar (C_{2h}) isomer could be potential candidates for HEDMs owing to their large dissociation energy and moderate dissociation barrier.

Gaseous nitryl azide N_4O_2 can be generated by the heterogeneous reaction of gaseous ClNO_2 with freshly precipitated AgN_3 at 223 K (-50°C) [44]. The geometric and electronic structure of the molecule in the gas phase has been characterized by *in situ* photoelectron spectroscopy (PES) and quantum chemical calculations. The experimental first vertical ionization energy of N_4O_2 is 11.39 eV, corresponding to the ionization of an electron on the highest occupied molecular orbital. An apparent vibrational spacing of $1600 \pm 60 \text{ cm}^{-1}$ on the second band at 12.52 eV further confirmed the preference of an energetically stable linear chain structure in the gas phase. Both calculations and spectroscopic results suggested that the molecule adopts a *trans*-planar chain structure, and a five-membered ring decomposition pathway is more favorable.

In addition to the nitryl azide configuration, the nitrogen oxides with a gross formula N_4O_2 could also exist in the form of a tetrazetane dioxide:

CAS RN [119708-60-0]
Tetrazetane-1,3-dioxide

A method for stabilizing polyheteroatomic rings containing only N atoms was proposed via introduction of acceptors for the unshared electron pair on the heteroatom, especially atoms of O, thus giving N-oxides. The stability of tetrazete-1,3-dioxide has been calculated by a Modified Neglect of Diatomic Overlap (MNDO) method [45].

In fact, the N_4O_2 system has a completely planar structure and computed heat of formation of 523 kJ/mol (125.0 kcal/mol). Furthermore, the system appears to be kinetically stable with a barrier to unimolecular dissociation of 187 kJ/mol (44.8 kcal/mol), respectively [18]:

CAS RN [140928-94-5]
1,4-Dioxo-2,3,5,6-tetrazine

Valence bond representations for the decomposition reactions of N_3NO and N_3NO_2 based on standard Lewis and increased-valence structures showed that the electronic reorganizations that are associated with the use of these two types of structures involved electron-pair delocalizations and one-electron delocalizations, respectively, which afforded polar and non-polar representations for the decompositions [32].

The conformational and structural stability of nitryl azide $NNN-NO_2$ and nitrosyl azide $NNN-NO$ were investigated by DFT and *ab initio* calculations [40]. The $-NO_2$ rotational barrier in nitryl azide was predicted from the symmetrical potential function to be about 29.3 kJ/mol (7 kcal/mol). The vibrational frequencies were calculated and the predicted IR and Raman spectra of the *cis-trans* mixture were plotted. Complete vibrational assignments were made on the basis of normal coordinate calculations for the stable conformers of both nitrosyl azide and nitryl azide.

9.7 Dinitramidoamine Anion N_5O_4^-

A new nitrogen-oxygen anion, similar to dinitramide, has been postulated and a synthesis attempted. The properties of the ammonium salt of 1,3-dinitrotriazene, dinitramidoamine, di(nitramido)amine, 1,1,5,5-tetraoxoazapentene(2) have been predicted based on its similarity with ADN, and it was hoped that this would be an environmentally friendly, non-toxic replacement for AP. This as yet unobtainable new salt is also known under its acronym, ADNA. The difference between the new salt and ADN would be only two additional nitrogen atoms inserted between the two nitro groups. The structure of ADNA was expected to be

The density was predicted to be 1.76 g/cm^3 , and the enthalpy of formation was predicted to be $+180 \text{ kJ/mol}$ ($+43 \text{ kcal/mol}$). Synthesis efforts with nitrourethane as an intermediate have not yet been successful [46]. It seems highly premature to start worrying about the possible environmental impacts of a chemical that is so unstable that it cannot even be obtained in milligram quantities in the laboratory. The computational methods used for predicting toxicity and environmental impact look very nice but in reality are useless [47, 48].

9.8 Polyazine N-oxides

After most attempts to calculate the predicted heats of formation and stability of polynitrogens had failed to reveal the hoped-for relatively stable HEDM, it was noted that adding oxygen to all-nitrogen compounds would actually stabilize them and at the same time make them more useful as oxidizers in rocket propellants.

The $\text{N}^+ \rightarrow \text{O}^-$ semipolar bond linkages in polyazine nitrogen oxides, if appropriately located, may diminish the destabilization associated with nitrogen catenation. Forty nitrogen oxides of isomeric diazines, triazines, and tetrazines have been computationally characterized in terms of their geometries, relative energies, and (for a representative selection) electrostatic potentials [49]. The presence of $\text{N}^+ \rightarrow \text{O}^-$ linkages does partially counteract the destabilizing effects of nitrogen catenation, although the isomers with complete catenation remain the least stable. The stabilizing influence of $\text{N}^+ \rightarrow \text{O}^-$ groups, and the accompanying changes in bond lengths, can be understood in terms of resonance charge delocalization to the polyazine rings. The

N(O)—N(O) bonds between nitrogens that both bear oxygens tend to be relatively weak. The electrostatic potentials above the polyazine rings become increasingly positive because there are more nitrogens and oxygens; eventually they are positive above all of the carbons and nitrogens and possibly even the oxygens, with negative regions only on the peripheries of the molecules. However, the nitrogens that bear oxygens always have more positive potentials than those that do not. The predicted crystal densities of three tricyclic polyazine nitrogen oxides (one structure shown as an example, but the N=O bonds should be shown as semipolar $\text{N}^+ \rightarrow \text{O}^-$ bonds)

range from 1.96 to 2.03 g/cm³ [50]. The calculated solid-phase enthalpies of formation were between 135 and 314 kcal/mol. The computed detonation velocities and detonation pressures were similar to HMX for two of the compounds and significantly greater for the third, exceeding even CL-20. All three compounds were expected to be less impact sensitive than both HMX and CL-20.

9.9 Nitrohydrazine and Dinitrohydrazines

Nitrohydrazine and dinitrohydrazines have not yet been synthesized and at this time remain purely speculative. Combining the energy of the N—N bonds in hydrazines with the oxidative power of nitro groups should make a good oxidizer. As part of a series of investigations into unusual molecules of potential application to high-energy materials, a series of calculations to determine the optimized structures, geometric parameters, and vibrational frequencies and predict fundamental thermodynamic properties of nitrohydrazine and two dinitrohydrazine isomers was performed [51].

10 Other Nitrogen-Oxygen-Halogen Compounds

Many oxidizers are built around the nitrogen atom as the central atom. Nitrogen is capable of forming strong bonds, single, double, and semipolar bonds with oxygen. Nitrogen also forms bonds, not always stable bonds, and often labile bonds with halo-

gens. Several NO_xX compounds with $x = 1, 2$, or 3 and $X = \text{F}$ were already discussed in *Encyclopedia of Oxidizers*, in the chapter “Nitrogen Fluorides.”

Perchlorates are the most widely used solid propellant oxidizers in rocket propellants. So one would want to combine the perchlorate or chlorate group with nitrogen as the central atom. A good oxidizer, if it can be prepared and stabilized, would be $\text{N}(\text{ClO}_4)_3$.

10.1 Nitrosyl and Nitryl Compounds

Some nitrosonium and nitronium compounds, e.g., the fluorides and chlorides, are liquids and have more covalent bond character. Some of them were already discussed in *Encyclopedia of Oxidizers*, in the chapter “Nitrogen Fluorides.” Nitrosonium and nitronium compounds have more saline character and are solids at room temperature. That is one reason why some chemists suggest that the words *nitryl* and *nitronium* should designate two different forms of NO_2 : a covalent bond bound form and an ionized salt form. The same holds for nitrosyl and nitrosonium.

10.2 Nitrosonium and Nitronium Compounds

In organizing the vast amount of information on rocket propellant oxidizers, a decision had to be made as to whether nitrosonium and nitronium oxidizer salts should be discussed under nitrogen oxides, from which the cation is derived, or under various chapters for anions like perchlorate and tetrafluoroborate. A similar decision had to be made for the oxonium salts. It was decided to give the cations priority over the anions for the simple reason that we are used to listing the cation part of salts first and the anion part last. But then this chapter on nitrogen oxides had grown to a point where it needed to be subdivided. For this reason detailed discussion of nitrosonium and nitronium perchlorate oxidizer salts was moved to the end of the chapter “Perchlorate Salts” in the discussion on perchlorates. These compounds did not deserve a separate chapter for themselves.

10.2.1 Nitryl Cyanide

Cyanide is a pseudohalogen. Thus, it should be able to form analogs to nitrosyl chloride or nitryl chloride in which the halogen is replaced by a pseudohalogen. The elusive nitryl cyanide, O_2NCN , has been synthesized and characterized by the reaction [52, 53]

It was prepared in good yield, characterized by NMR and vibrational spectroscopy, and studied by theoretical calculations. Nitryl cyanide was separated from unwanted byproducts by fractionated condensation and condensed at 161 K (−112°C). NCNO₂ is colorless in the solid state and in the gas phase. It melts to a colorless liquid at 188 K (−85°C). Small amounts of nitrogen oxides may give it a pale yellow or bluish color. A density of 1.24 g/cm³ was measured for the liquid at 194 K (−79°C). The vapor pressure of NCNO₂ was measured between 169 and 273 K (−96 and 0°C), giving an extrapolated boiling point of 280 K (+7°C) and an enthalpy of evaporation of 28.4 kJ/mol (6.8 kcal/mol). The enthalpy of formation of liquid NCNO₂ was predicted to be +184 kJ/mol (+43.9 kcal/mol). The question was how stable it would be. Pure NCNO₂ is stable at room temperature. Heating for 1 h to 323 or 373 K (50 or 100°C) resulted in only slight decomposition, with most of the NCNO₂ being recovered unchanged, and heating to 413 K (140°C) for several hours was required to achieve complete decomposition. Homolytic bond dissociation into NO₂ and CN free radicals was predicted to correspond to an enthalpy change of 259 kJ/mol (62 kcal/mol). It is assumed that the bond between the NO₂ and the CN part of the molecule is more a covalent bond than that in a saline ionic compound. Nitryl cyanide holds promise as a HEDM and might also prove useful as a HEDM building block.

10.2.2 Nitronium and Nitrosonium Oxalates

In the search for more energetic chlorine-free oxidizers, the enthalpies of formation of the four theoretical compounds bis(nitrosonium) oxalate, bis(nitronium) oxalate, and their covalent ester isomers in the solid state were predicted by computational chemistry (Table 2) [54, 55]. This was done as an example of how computational chemistry can be used as a precursor to actual laboratory work in the search for more energetic and environmentally benign rocket propellants. The predicted specific impulse of mixtures of nitronium oxalate with aluminum was comparable to that of AP/Al mixtures.

Table 2: Predicted enthalpy of formation of nitronium and nitrosonium oxalates.

Compound	Gross formula	Theoretical enthalpy of formation, kcal/mol	Oxygen balance, %
[NO ₂ ⁺] ₂ [COO [−]] ₂	C ₂ N ₂ O ₈	−86.6	+35.5
[NO ⁺] ₂ [COO [−]] ₂	C ₂ N ₂ O ₆	−107.0 ^a	+21.6
O ₂ N—O—CO—CO—O—NO ₂	C ₂ N ₂ O ₈	−113.5 ^a	+35.5
ON—O—CO—CO—O—NO	C ₂ N ₂ O ₆	−96.5	+21.6

Data source: [55]

^aCompounds with the more negative enthalpy of formation were predicted to be the more stable ones.

These compounds would have a very positive oxygen balance, but they have not yet been synthesized. Comparing the ionic versus the covalent isomers, those with the more negative enthalpy of formation were predicted to be the more stable ones.

10.2.3 Nitrosonium Tetrafluorochlorate

Another potential oxidizer and intermediate in the synthesis of other nitrosonium salts is nitrosonium tetrafluorochlorate, $\text{NO}^+\text{ClF}_4^-$ [56]. This is similar to nitrosonium perchlorate, except the oxygens in the anion were replaced by fluorine. It can be prepared by the reaction of nitrosyl fluoride and chlorine trifluoride at temperatures below 273 K. The compound is a white, crystalline solid and a powerful oxidizer. It ignites hypergolically with many organic fuels. The enthalpy of formation was estimated as $\Delta H_f^{298} = -287 \text{ kJ/mol}$ (-68.6 kcal/mol). Attempts to prepare nitronium tetrafluorochlorate were unsuccessful.

10.3 Other Nitrogen-Oxygen-Halogen Compounds

New covalent inorganic perchlorates were prepared from chlorine perchlorate. The compound $\text{I}(\text{ClO}_4)_3$ was partially characterized and nitrogen triperchlorate $\text{N}(\text{ClO}_4)_3$ deduced as a short-lived primary reaction product. The one-valent iodine(I) perchlorate could not be prepared, but a complex perchlorate of iodine(III), $\text{CsI}(\text{ClO}_4)_4$, was indeed synthesized [57].

Nitromethanes

The topic of nitro compounds had to be distributed over 4 chapters because it would have been a very large chapter that would have made it more difficult for readers to find information on a specific compound and it would have been difficult to arrange 30 chapters among 5 subvolumes so that each subvolume is about the same size. That spacial arrangement was made easier by dealing with smaller chapters.

This chapter is part of the group of three chapters on nitroaliphatic compounds. The topic of nitroaliphatic compounds had to be subdivided into an introduction, the chapter entitled “Nitro Compounds“, the “Nitromethanes“ chapter at hand which covers nitroaliphatic compounds with only one carbon atom, and a chapter on “Nitroaliphatic Compounds“ which contains information on nitroaliphatic compounds with more than one carbon atom.

1 Nitroaliphatic Compounds (Nitroalkanes)

Nitroaliphatic compounds (also called nitroalkanes or nitroparaffins) are produced from alkanes or alkenes and nitric acid or dinitrogen tetroxide (a potentially explosive mixture) which is a very hazardous operation [1]. They are widely used as intermediates in the chemical process industry [2, 3] and as solvents for nitro lacquers.

Supplement 1 to *Tetrahedron* volume 19 (Jun 1963) contains a series of publications on nitroparaffins. The following year another supplement to *Tetrahedron* collected papers presented at an international conference on nitro paraffins in 1963 [4].

This introductory chapter summarizes properties of nitroalkanes as a family group. Individual nitroalkanes are discussed in dedicated sections further down. If we did not discuss the common properties of nitroalkanes as a group as we do it here, some of the typical properties of nitroalkanes which are shared by all nitroalkanes would have to be discussed where they are first encountered under nitromethane, the lowest and most frequently used member of the group, or in later sections. As an introduction, this chapter gives summary tables that make it easier to compare properties of different homologous nitroalkanes that only differ by a CH_2 group or are structural isomers.

The development of energetic compounds continues unabated into the current century, and before chemists can synthesize more energetic materials they need to understand the chemistry of simple nitro compounds. It is with this fundamental need in mind that we have assembled here a fairly thorough collection of references relating to making nitro compounds and using them safely.

Aliphatic nitroalkanes can be subdivided into six groups depending on their molecular structure:

Primary nitroalkanes	RCH_2NO_2
Secondary nitroalkanes	$\text{R}'\text{R}''\text{CHNO}_2$
Tertiary nitroalkanes	$\text{R}'\text{R}''\text{R}'''\text{CNO}_2$
Geminal dinitroalkanes	
Terminal gem-dinitroalkanes	$\text{RCH}(\text{NO}_2)_2$
Internal gem-dinitroalkanes	$\text{R}'\text{C}(\text{NO}_2)_2\text{R}''$
Vicinal dinitroalkanes	$\text{R}'\text{CH}(\text{NO}_2)\text{CH}(\text{NO}_2)\text{R}''$
Trinitromethylalkanes	$\text{R}'\text{R}''\text{CHC}(\text{NO}_2)_3$

1.1 Production of Mononitroalkanes

Nitroalkanes can be prepared by direct nitration of aliphatic or alicyclic hydrocarbons with either nitric acid or nitrogen dioxide or dinitrogen pentoxide in the vapor phase at elevated temperatures but this is a very hazardous operation since one is essentially feeding rocket propellants into a reactor just short of ignition or explosion conditions. Dilution with inert gases helps to prevent a disaster. These free radical reactions typically do not give one specific product but result in mixtures of nitro compounds with varying stages of nitration and nitro groups attached to different carbon atoms in the molecule [5]. These product mixtures then have to be separated by fractionated distillation or extraction. In $\text{C}_{>2}$ hydrocarbons, tertiary carbons are nitrated most readily, followed by secondary and primary carbon atoms in that order, which are less reactive. At the higher temperatures, hydrocarbon chains are often broken and nitroalkanes with less carbons than the starting alkane are formed along with the intended product. For instance, nitration of propane results in a mixture of 2-nitropropane, 1-nitropropane, 2,2-nitropropane (a trace), nitroethane, and nitromethane. A good summary is the book *Synthetic Routes to C-Nitro Functionality* [6]. See also [7–9].

The hydrogens adjacent to nitro groups, in particular those adjacent to two or three nitro groups are quite acidic. These compounds can act as acids and form salts with strong bases. Many of these solid salts can be used as ingredients in solid propellants.

Because some nitroalkanes are used as solvents and as intermediates in organic synthesis, the physical properties of nitroalkanes are well characterized and the data are fairly accurate. Several summaries of the physical and chemical properties of nitroalkanes have been published as summarized in Table 1.

Table 1: Summary of publications on physical and chemical properties of nitroalkanes.

Topic	Author	Year	Pages	References
Aliphatic nitro compounds	Levy and Rose	1947	37	[10]
Nitroparaffins	Toops	1956	3	[11]
Nitration of hydrocarbons	Topchiev	1959	329	[12]
Nitration methods and mechanisms	Olah, Malhotra, and Narang	1989	330 + xii	[13]

Data source: [16]

1.2.1 Freezing Points of Mononitroalkanes

The freezing points of mononitroalkanes are listed in Table 3. A method has been developed to predict melting/freezing points of nitroaliphatic compounds from the molecular mass and molecular structure [17]. The list of examples comparing predicted freezing/melting points to measured data included 13 nitroaliphatic compounds. The average deviation of predicted temperature from measured temperatures was 5.4%. See also reference [18]. These methods are based on the elemental composition of energetic compounds and the contributions of some specific polar groups/structural moieties as additive and non-additive functions, respectively.

Table 3: Freezing points of mononitroalkanes.

Compound	Freezing point	
	K	°C
Nitromethane	244.60	−28.55
Nitroethane	183.63	−89.52
1-Nitropropane	169.16	−103.99
2-Nitropropane	181.83	−91.32
1-Nitrobutane	191.82	−81.33
2-Nitrobutane	Glass formation	
1-Nitro-2-methylpropane	196.30	−76.85

Data source: [11]

1.2.2 Boiling Points of Mononitroalkanes

The boiling points and other physical properties of mononitroalkanes are listed in Table 4. A similar list of boiling points of mononitroalkanes is given in Table 5.

1.2.3 Densities of Mononitroalkanes

The densities of nitroalkanes as a function of temperature can be calculated from the equation

$$\rho = c - dt$$

where ρ is the density in g/cm^3 , t is the temperature in $^{\circ}\text{C}$ and c and d are the constants listed in Table 6. Another source gives a list of densities and temperature coefficients of a series of mononitroalkanes as shown in Table 7.

Table 4: Physical properties of mononitroalkanes.

Compound	Density, g/cm^3	Viscosity, cPs	Boiling point T_b , K	Surface tension, dyn/cm	Parachor	Critical temperature T_c , K	T_b/T_c
Nitromethane	1.13118	1.37872	375.0	36.78	132.7	622.7	0.60
Nitroethane	1.03819	1.39015	387.9	31.31	171.0	661.8	0.59

2-Nitro-2-methyl-propane	Solid	Solid	0.95028	0.001128

Data source: [11]

For some applications of nitroalkanes, such as in explosives, the density is an important performance parameter. Densities of nitroalkanes can be determined experimentally or can be predicted theoretically. One of the first predictive methods was based on the group additivity method [20], comparing predictions for 173 energetic compounds with experimental results.

Correlations to predict crystal density based on two different models were introduced for 82 different energetic compounds including 13 nitroaliphatic compounds whose molecules contained functional groups common to CHNO explosives [21–23]. Additional work expanded the list of energetic materials to 172 compounds [24]. Root mean square (rms) deviations for acyclic and cyclic nitramines were worse than for nitrate esters and nitroaliphatic explosives. This method is a simple procedure for calculating crystal density of energetic compounds and gave good results as compared to group additivity methods for estimating the density of organic explosives. The predictions are less accurate for liquid nitroalkanes.

1.2.4 Vapor Pressures of Nitroalkanes

Table 8 is a summary of vapor pressure data for nitroalkanes.

Table 8: Vapor pressures of nitroalkanes.

Temperature, °C	Vapor pressure, mm Hg							
	Nitro-methane	Nitro-ethane	1-Nitro-propane	2-Nitro-propane	1-Nitro-butane	2-Nitro-butane	1,1-Dinitro-propane	2,2-Dinitro-propane
10	16.12	8.52	3.96	7.05	1.23	2.79		
20	27.89	15.65	7.52	12.99	2.50	5.48		
25	36.26	20.89	10.00	17.27	3.50	7.46

180								659.0

Data source: [16]

The constants for the Antoine equation for the calculation of the vapor pressures of eight different mononitroalkanes are given in reference [11].

1.2.5 Viscosities of Mononitroalkanes

Viscosities of mononitroalkanes are listed in Tables 2 and 4 above.

1.2.6 Surface Tensions of Mononitroalkanes

The surface tensions of nitroalkanes as a function of temperature can be calculated from the equation

$$\gamma = a - bt$$

where γ is the surface tension in dyn/cm, t is the temperature in °C, and a and b are the constants listed in Table 6 above. Surface tensions at 298 K are listed in Table 4 above.

1.2.7 Refractive Indices of Mononitroalkanes

Refractive indices of mononitroalkanes were already contained in Table 2 above. Additional data for refractive indices of eight different mononitroalkanes at three different temperatures are available in reference [11].

1.2.8 Spectra of Mononitroalkanes

An analysis of the dependence of the frequencies of the valence vibration on the position of the $-\text{NO}_2$ group and the structure of the substituent was conducted in a series of nitro compounds [25, 26]. The inductive and steric effects, as well as the effect of conjugation, influence the position of the band of the anti-symmetric valence vibration of the $-\text{NO}_2$ group. A linear dependence of the band of the anti-symmetric valence vibration on the induction constant of the substituent was found. The position of the band of the symmetrical vibration of the $-\text{NO}_2$ group is determined chiefly by the steric hindrances of the substituent.

Spectra of nitroalkanes are useful to identify internal structures of the molecules and to calculate thermodynamic properties. Specifically, rotation around the C—N axis contributes to the spectra and the stability of the molecule. Internal rotation in n -mononitroalkanes of the type $\text{CH}_3(\text{CH}_2)_n\text{NO}_2$, $n \leq 7$ was computed by density functional theory methods [27]. Conformations and 36 potential functions for all rotations were found. It was shown that as the hydrocarbon chain became longer, the potential functions that describe particular molecular fragments changed only negligibly beginning from a certain n .

Harmonic oscillator approximations are often used to calculate the partition function for low frequency modes that represent hindered internal rotation. Using harmonic oscillator approximations may lead to significant errors when internal rotation

of functional groups in molecules involves hindered or free rotation. Anharmonic oscillator approximation methods should be used for the proper reproduction of the energies of excited vibrational states, especially at high temperatures. A theoretical study using anharmonic oscillator approximation and explicit treatment of internal rotation was performed to explain the effect of internal rotation and anharmonic oscillator approximation on thermodynamic parameters of nitroethane and 1-nitropropane and 2-nitropropane [28].

1.2.9 Thermodynamic Properties of Nitroalkanes

Nitroalkanes are of interest either as rocket propellants by themselves or as models for other, more complex nitro compounds. Having accurate thermodynamic properties is important for predicting performance as a rocket propellant.

1.2.9.1 Summaries of Thermodynamic Properties of Nitroalkanes

Thermodynamic properties of selected nitroalkanes are listed in the individual sections below, starting with nitromethane and ending with more complex nitroalkanes that also contain other substituents in addition to hydrogen. There are several summaries of thermodynamic properties of nitroalkanes which can be consulted if additional data are needed.

1.2.9.2 Experimental Determination of Thermodynamic Properties of Nitroalkanes

The heats of combustion of six mononitroalkanes and four polynitroalkanes, including three sets of isomers, were determined experimentally in a combustion bomb calorimeter [16]. Because qualitative analyses of products of combustion gave no indications of the presence of oxides of nitrogen or nitric acid in the gaseous products of combustion, the products of combustion in all experiments were assumed to be gaseous carbon dioxide, gaseous nitrogen, and liquid water. Standard enthalpies of formation were calculated from the experimental energies of combustion as summarized in Table 9.

If one converts the heat of combustion of Table 9 from kcal/mol to kcal/kg as shown in Table 10, the effect of elongating the hydrocarbon chain on the heat of formation can be studied more easily.

If one correlates these data with the oxygen balance, the heats of combustion of nitroparaffins can be shown to follow a linear function of the oxygen balances of the molecules (Figure 1), and an equation was derived that relates these two variables with an average error of estimate of about 2% of the experimental values. An equation of the form:

$$\Delta E_{\text{comb}} = (26.418)(\text{oxygen balance}) - 1792.3$$

Table 9: Heat of combustion and enthalpy of formation of nitroalkanes.

Compound	Standard State	Heat of combustion $-\Delta E^\circ$		Enthalpy of formation ΔH_f		Molecular mass		Oxygen balance	
		kJ/mol at 298 K	kcal/mol at 25 °C	kJ/mol at 298 K	kcal/mol at 25 °C	g/mol	%		
Nitromethane	Liquid	735 ± 0.8	175.70 ± 0.18	-89 ± 0.8	-21.28 ± 0.18	61.04002		-39.3

Data source: [16]

Figure 1: Correlation between heat of combustion and oxygen balance of nitroalkanes (reprinted and modified from [16], with permission from © 1949 American Chemical Society; permission conveyed through RightsLink.)

was derived where ΔE_{comb} is expressed in kilocalories per kilogram. The numbers adjacent to the data points in Figure 1 are the numbers of the compounds listed in Table 10.

The standard molar enthalpies of vaporization or sublimation of 1-nitropentane and nitrocyclohexane were derived from vapor pressure measurements, and the standard enthalpies of formation of nitrocyclohexane were measured using combustion calorimetry [29]. The results were then compared to predictions based on additivity rules.

1.2.9.3 Computational Methods for Prediction of Thermodynamic Properties of Mononitroalkanes and Polynitroalkanes

Prediction of Enthalpies of Formation

Thermodynamic properties of simple nitroalkanes and difluoroamino alkanes can be predicted based on quantum-mechanical calculations. The heats of formation of a series of polyatomic molecules containing $-\text{NO}_2$ and/or $-\text{NF}_2$ groups have been determined using the isodesmic procedure of Pople et al. [30–32]. An excellent correlation between the semiempirical heats of formation and the corresponding available experimental data was observed. It was found that $-\text{NO}_2$ and $-\text{NF}_2$ groups have large and comparable destabilizing effects when it comes to evaluate the thermal stability of the molecules.

The well-known simple Benson method predicts the heats of formation of gaseous compounds by adding the contributions by individual bonds. Expanding on this method, a similar additive method was developed for estimating the gaseous heats of formation of energetic molecules containing $-\text{NO}_2$ and/or $-\text{NF}_2$ groups and its accuracy was checked against measured values taken from previously published sources [33].

The ideal gas (**not** condensed phase!) thermodynamic properties of 29 nitro and nitrate compounds, high explosives such as 2,4,6-trinitrotoluene (TNT), 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX, cyclotrimethylenetrinitramine), 1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane (HMX, octogen), pentaerythritol trinitrate (PETN), normal propyl nitrate (NPN), and glycerol trinitrate (GTN) and propellants were predicted from spectroscopic data and compared to calorimetric results reported in the literature [34, 35]. The fundamental vibrations, the bond lengths, and the moments of inertia of all the molecules were calculated using semi-empirical methods. The resulting thermodynamic properties were represented in a polynomial form, ready for use in rocket propulsion I_{sp} calculations. The format used was the OLD NASA CEC polynomial format and consisted of two sets of polynomial coefficients for each species [36]. The first set of seven coefficients represented the properties above 1000 K, and the second from 200 to 1000 K. Both polynomials gave the same values at 1000 K for the properties. The 15th (last) coefficient represented the enthalpy of formation $\Delta H_f(298)/R$. The results are summarized in Table 11.

Table 11: Ideal gas thermodynamic properties of nitro and nitrate compounds.

Gaseous (vapor) compound name	Formula	ΔH_f^{298} kJ/mol	S^{298} JK ⁻¹ mol ⁻¹	C_p^{300} JK ⁻¹ mol ⁻¹
Nitromethane	CH ₃ NO ₂	-80.75	282.86	55.77
Nitromethyl free radical	•CH ₂ NO ₂	152.47	288.22	59.08
Nitromethane	CD ₃ NO ₂	-61.79	291.67	63.45
Nitromethane	CD ₂ HNO ₂	-57.72	289.26	61.07

Data source: [35]

The established modes of interaction of nitro groups in nitro derivatives of methane in condensed and gaseous states along with data on the kinetics of their thermal decomposition provided a set of energies of dissociation of C—NO₂ bonds based on enthalpies of formation from research and literature data [37, 38]. These values enabled one to determine the enthalpies of formation of nitromethyl radicals and energy of dissociation of C—H bonds. The energies of dissociation of C—H bonds do not depend on quantity of nitro groups connected to atoms of carbon, as in the halogen derivatives of methane. The enthalpies of formation of radicals •CH₂NO₂, •CH(NO₂)₂, •C(NO₂)₃, ••CHNO₂, ••C(NO₂)₂, and •••CNO₂, and the energies of dissociation of —NO₂ groups from radicals of the nitro derivatives of methane were then calculated.

Thermodynamic properties, enthalpy (ΔH_f) and Gibbs energy (ΔG_f) of 21 energetic nitro compounds were predicted by computational methods [39]. The enthalpy and the Gibbs energy of formation obtained exceeded those reported in the literature. The calibrated least-squares parameters and parametric equations were used to predict ΔH_f and ΔG_f for five newly developed energetic nitro compounds for further applications.

The heats of formation of CH_3NO_2 and $\text{CH}_2=\text{CHNO}_2$, as well as anions derived from some of the molecules, have been calculated using *ab initio* molecular orbital theory [40].

The standard enthalpies of formation at 298 K and heat capacities and entropies in the temperature range of 300–5000 K for a range of nitro compounds were computed by means of a density functional theory in quantum chemistry [41].

Heats of formation of condensed phase nitroalkanes, nitrate esters, and nitramines can be interpolated from a collection of measured heats of combustion of different energetic materials based on elemental composition and various structural and functional group parameters of CHNO energetic compounds [42]. This method can provide predictions for energetic compounds compared to the calculated outputs of the best empirical and complex quantum mechanical methods [43].

The heats of formation of nitro compounds can be calculated by a semi-empirical molecular orbital (MO) method, although in the case of polynitro compounds, differences between observed and calculated values become slightly larger. By combining heats of vaporization and sublimation obtained by the additivity rule with ΔH_f° in gas phase obtained by other methods, ΔH_f° in condensed phase could be estimated with sufficient accuracy [44, 45].

The C– NO_2 bond dissociation energies and the heats of formation of nitromethane and polynitromethanes (dinitromethane, trinitromethane, and tetranitromethane) in gas phase at 298.15 K were calculated theoretically using density functional theory and other methods in combination with different basis sets [46]. It was found that the accuracy of C– NO_2 bond dissociation energies can be improved by switching to different functionals. As the number of NO_2 groups on the same C atom increases, one functional performed better than the other functional. All four functionals yielded satisfactory predictions for the enthalpy of formation in the gas phase with deviations of <2 kcal/mol from experimental ones for $\text{CH}_2(\text{NO}_2)_2$ and $\text{CH}(\text{NO}_2)_3$. For the $\text{C}(\text{NO}_2)_4$ molecule, a different basis set augmented with polarization functions and diffusion functions was required to yield a good result.

The gas phase enthalpies of formation of mononitromethane, dinitromethane, trinitromethane, and tetranitromethane and nitroethane, as well as of their nitrite and *aci*-form isomers, and the enthalpies of the C–N bond dissociation and isomerization of these nitroalkanes were calculated using different multi-level and density functional theory (DFT) based methods [47]. The calculated values of the formation and reaction enthalpies were compared with experimental data wherever these data were available. It was found that only the G3 procedure gave accurate (within 1 kcal/mol) results for the formation enthalpy of nitroalkanes, their isomers and radical products. The G3 procedure and two new hybrid meta-DFT methods proposed by Truhlar's group [48] showed good results for the reaction enthalpies of the nitromethane isomerization and the C–N bond dissociation. The results can be used to analyze thermodynamics of the dissociation and isomerization reactions of the polynitro-substituted methanes.

The gas-phase enthalpies of formation of 57 aliphatic nitro compounds and nitramines (mononitro and polynitro compounds including cyclic compounds and well-known explosives such as hexogen, octogen, and CL-20) were calculated using the Gaussian-4 (G4) theory applied to atomization and isodesmic reaction energies [49]. It turned out that the $\Delta H_f^{298}(\text{G})$ values calculated from the atomization reactions were underestimated by an average of 10 kJ/mol, and they could not be used for the assessment of inaccuracies in the experimental enthalpies of formation. Much better agreement between theory and experiment was obtained using the isodesmic reaction procedure. Several isodesmic reactions were investigated for each compound. High accuracy of most experimental data was confirmed by the agreement with theoretical results. The differences between the calculated and the experimental enthalpies of formation in the range from 8 to 53 kJ/mol were attributed to possible errors in the experimental values for 17 compounds. The theoretical $\Delta H_f^{298}(\text{G})$ values were recommended for these compounds as being more reliable than the experimental values. A reference data set of internally consistent gas-phase enthalpies of formation of nitro compounds and nitramines was provided. Both experimental and calculated values were included in this data set. In addition, the enthalpies of sublimation or vaporization were evaluated for some compounds by taking into account the literature data on the condensed phase enthalpies of formation and the $\Delta H_f^{298}(\text{G})$ values recommended in this work. Thus, a set of self-consistent values of the enthalpy of formation in both condensed and gaseous phases and the enthalpy of sublimation or vaporization could be obtained for most of nitro compounds studied.

While most theoretical computations give only the predicted gas phase enthalpies of formation of nitro compounds, a different methodology will give the enthalpies of formation even in the condensed state. An additive method for predicting the standard heats of formation at 298 K of aliphatic and alicyclic polynitro-compounds in the condensed state consists of three steps: **(1)** the evaluation of the enthalpy of formation in the gaseous state, **(2)** the estimation of the enthalpy of vaporization for a liquid or enthalpy of sublimation for a solid and **(3)** the calculation of interaction terms, mainly between NO_2 groups [50, 51]. The uncertainties of predicted values turned out to be within only a few kcal/mol. As an example of application for the enthalpies of formation, it was shown that the theoretical specific impulse of high-energy solid propellants could be calculated with a relative uncertainty of less than 1%.

Prediction of Heat of Combustion

A method for estimating the gross and net heats of combustion of nitroaliphatic compounds and nitrate esters was based on elemental compositions as well as the presence of some specific polar groups and molecular fragments [52]. The method can be used for organic compounds with at least one nitro, nitramine or nitrate functional groups. The predicted results showed that this method gives reliable predictions of

heats of combustion with respect to the group additivity method and computed values based on atom-type electrotopological state indices.

1.2.9.4 Heat of Evaporation of Mononitroalkanes

Table 12 is a summary of the latent heats of evaporation of nitroalkanes.

Table 12: Latent heats of evaporation of nitroalkanes.

Compound	Latent heat of evaporation at 298 K = 25 °C	
	kJ/mol	kcal/mol
Nitromethane	38.0 ± 0.4	9.09 ± 0.09
Nitroethane	41.6 ± 0.4	9.94 ± 0.10
1-Nitropropane	43.4 ± 0.4	10.37 ± 0.10
2-Nitropropane	41.3 ± 0.4	9.88 ± 0.10
1-Nitrobutane	48.6 ± 0.5	11.61 ± 0.12
2-Nitrobutane	43.8 ± 0.4	10.48 ± 0.10
1,1-Dinitropropane	62.5 ± 0.6	14.93 ± 0.15

Data source: [16]

1.3 Chemical Properties of Mononitroalkanes

The most important chemical reaction of mononitroalkanes is the formation of aci-salts with alkalis. In most cases, the aci-salts are more reactive than the parent acid.

Nitroparaffins can be reacted with formaldehyde to obtain nitro alcohols, which can be further esterified with nitric acid (e.g. in the synthesis of nitroisobutylglycerol trinitrate or nitromethylpropanediol dinitrate).

1.3.1 Thermal Stability and Decomposition of Mononitroalkanes

Nitro compounds are of interest as energetic chemicals in propellants and explosives. As such, it is very important to have a thorough understanding of the decomposition of these compounds, both the unintended decomposition during storage, often at above nominal temperatures in tropical climates, and the intended, carefully controlled decomposition in a rocket chamber. The threshold of autoignition of nitroalkane vapors in the presence and even in the absence of air is an important safety parameter.

Nitro compounds may decompose via two different mechanisms: a molecular mechanism, when a molecule of HNO_2 is detached and the corresponding alkene is formed, and a free radical mechanism, in which the reaction starts with the breaking of the C—N bond. A study of the reactions of the former type is of considerable interest in the light of the general theory of elimination reactions in the gas phase. The radical decomposition of nitroalkanes is characterized by high values of the pre-exponential

factors [53]. The activation energy in this instance equals the energy for breaking the bond. Secondary reactions have little influence on the rate of radical decomposition of *gem*-polynitroalkanes, therefore the study of the kinetics of the decomposition can be an effective method of determining the energy for the breaking of the C–N bond in these compounds.

The contribution of the heterogeneous reaction to the rate of the gas phase decomposition of nitroethane, 1-nitropropane and 2-nitropropane was determined by varying the ratio of the surface to the volume of the reaction vessel [54]. The activation energies of the homogeneous decomposition of these compounds differed from the literature data obtained by different methods.

An analysis of experimental data on the decomposition of aliphatic nitro compounds revealed effects of the structure of the molecule and substituents in the alkyl group on the pre-exponential factor of the reaction rate constants and activation energies [55]. The pre-exponential factor and activation energy of 28 nitroalkane compounds were compared to their molecular structure and substituent effects in the alkyl group. The value of the pre-exponential factor depends on the contribution of three factors, manifested in the formation of the activated complex: liberation of the internal rotation relative to the dissociating C–N bond, a decrease in the frequencies of the deformational vibrations associated with this bond and rotation of the alkyl groups next to the reaction center. Empirical rules were noted: 1) in the series $\text{RCH}_n(\text{NO}_2)_{3-n}$, activation energy does not depend on the length of the alkyl chain R. For $n = 1$, $E = 197\text{--}201 \text{ kJ/mol} = 47\text{--}48 \text{ kcal/mol}$; for $n = 0$, $E = 172\text{--}178 \text{ kJ/mol} = 41\text{--}43 \text{ kcal/mol}$; 2) substituents R, H, and F in the α -position to the nitro group have the same influence on the activation energy; 3) when one NO_2 group is replaced by Cl, the activation energy is reduced by approximately 4 kJ/mol (1 kcal/mol); 4) Br and I reduced the activation energy to a greater degree than Cl.

The thermal decomposition of dilute *n*-nitroalkanes (nitromethane, 1-nitropropane = CAS RN [108-03-2], 2-nitropropane = CAS RN [79-46-9]) vapors (0.005–0.3 vol.-% diluted with air) in shock tubes was followed by recording the IR spectra of these compounds and their decomposition products [56]. A 1st-order rate law was followed and NO_2 was a primary dissociation product. The rate constants could be correlated with the C–N bond dissociation energy.

The pyrolysis of the alkyl radical sources RNO_2 ($\text{R} = \text{C}_1\text{--C}_6$ alkyl) in incident and reflected shock waves was examined at 900–1400 K and 1–30 atm by measuring NO_2 concentration profiles and deriving RNO_2 and $\text{R}^\bullet$ dissociation kinetic data [57]. The reactions behind the shock waves were followed by recording light absorption-time profiles of the decomposing molecules and the produced NO_2 . In addition, there are three earlier, separate publications by the same authors on MeNO_2 [58], EtNO_2 [59] and PrNO_2 [60] that will be discussed in more detail further down in this chapter.

These shock tube tests were similar to those conducted by other investigators later [61]. The thermal decomposition of dilute mixtures (0.2% by volume) of R-NO_2 ($\text{R} = \text{C}_2\text{H}_5$, *i*- C_3H_7 , *tert*- C_4H_9) in argon was investigated in the temperature

range 800–1000 K by a comparative rate method using ethyl bromide and isopropyl bromide as internal standards. Under these experimental conditions, the decomposition proceeded via C–N fission in competition with five-center elimination of HONO. The obtained values of activation energies were then compared with those obtained from thermochemical calculations. Comparisons of the reactions in the pyrolysis of nitro compounds, nitroso compounds and alkyl nitrates were published in [62, 63].

The influence of molecular structure on the rates and mechanisms of the gas-phase reactions of aliphatic nitro compounds and the structures of the transition states in the C–N dissociation and HNO_2 elimination processes were examined [64]. The characteristic features common to the decomposition of C-nitro compounds in the condensed phase are described, based on the C–N bond dissociation energy and the influence on the latter exerted by electronic, steric, and conformational effects. A bibliography included 86 references.

A relationship has been derived between the activation energies E_a of low-temperature non-autocatalyzed thermolysis of nitroparaffins and their oxygen balances [65]. An analogous relationship has also been found for pre-exponents of $\log A$. A direct relationship existing between E_a values and the impact sensitivity of the nitro compounds in a condensed state was confirmed by the first relationship. From these two relationships, the molecular structural dependences of the thermal reactivity of nitroparaffins in both gaseous and liquid states can be correlated. For the thermolysis of mononitromethane in the liquid state, a primary homolytic pseudo-monomolecular fragmentation decomposition mechanism was proposed.

Structure-property correlation equations for the activation energies of thermal decomposition of nitro compounds in the gas phase can be obtained based on structural descriptors [66]. Correlation equations were constructed using a computing program based on data for 90 nitro compounds belonging to various chemical classes.

Geometric molecular structure parameters of nitro and fluoronitro derivatives of nitromethane, nitroethane, 1-nitropropane, and 1-nitrobutane (for which experimental data on kinetics of radical gas-phase decomposition were available) have been determined by a computational method [67, 68]. Correlations between changes in logarithms of the activation energy and those in the lengths of C–N – and C–H-bonds as well as in the ionization potentials have been found. The major changes in the C–N- and C–H bonds occurred when bulky atoms and groups (NO_2 , Cl, Br, and I) were introduced into the molecules. An equation was derived which allowed one to perform a high-accuracy determination of the activation energy for radical gas-phase decomposition of nitroalkanes using the coefficients of steric interactions in the molecules calculated by methods of molecular mechanics. In attempting to explain the abnormally low thermal stability of dinitromethane, a mechanism was suggested that included the elimination of water from the aci-form of dinitromethane.

A theoretical study of the formation and destruction of the aci-forms of nitromethane and dinitromethane based on a quantum chemical study of the dehydration mechanism of CH_3NO_2 and $\text{CH}_2(\text{NO}_2)_2$ molecules has shown that a water

molecule eliminates from the respective *aci*-forms, formation of the latter being the rate-limiting step of the whole process [69].

Data from experimental and theoretical studies of thermal decomposition of C-nitro and N-nitro compounds of aliphatic, alicyclic, aromatic and heteroaromatic compounds, which formed the basis for the development of an *ab initio* approach to the prediction of the mechanisms of thermolysis of energetic compounds, were used to develop relationships between the structures and thermolysis mechanisms of nitro compounds [70]. Using the Recombination Reaction Network strategy and Computer Assisted Structure Building software, full reaction mechanisms for the thermal destruction of nitro compounds at different thermal decomposition levels (including extensive ones) could be simulated and the full set of possible mechanisms of thermal decomposition of 38 chemically different nitro compounds was presented.

A relationship has been derived to predict the activation energies (E_a) of low-temperature non-autocatalyzed thermolysis of nitroparaffins through suitable combination of elemental composition [71]. This correlation of E_a was based on experimental data using the isothermal monomethric method, which is useful method to examine the kinetics of thermolysis of energetic materials in vacuum. This method used the optimized numbers of carbon, hydrogen and oxygen divided by the molecular weight of nitroparaffins to obtain a reliable correlation. This correlation is a general relationship because it can be applied for various nitroparaffins as compared to previous methods which used oxygen balance for some specific groups of compounds. A similar predictive method can be used to predict the autodetonation temperature of nitro compounds [72]. The pyrolysis of nitroalkanes and nitroarenes is described in [73].

1.3.2 Reactions of Mononitroalkanes

Substitution of hydrogen in the alkyl group in nitroalkanes does not always result in the desired products. The types of products are less predictable than for reactions with halogenoalkanes [74]. The main difference is that many nitro compounds react in the *aci*-form because the hydrogen in the alpha-position is activated by drawing electrons away from it.

Methyl groups are usually electron-donating relative to hydrogen when introduced into molecules, and their consequent acid-weakening properties are well known. Methyl substitution at the α -position of nitroparaffins, however, has quite the opposite effect: for example, in the simple series nitromethane, $pK_a = 10.22$, nitroethane, $pK_a = 8.60$, and 2-nitropropane, $pK_a = 7.74$, a marked increase in acidity accompanies methyl substitution [75]. 2-Nitropropane was the strongest acid from a group of ten $C_{n \geq 2}$ nitroalkanes. Similar data in Table 13 show that the acidity constant of mononitroalkanes decreases (i.e., acidity increases) with increasing length of the alkyl chain. In a typical example, the pK_a values of RCH_2NO_2 decreased in the order $CH_3NO_2 > CH_3CH_2NO_2 > (CH_3)_2CHNO_2$ in water, whereas the rate of proton

abstraction by hydroxide ion decreased in the same order. This phenomenon is sometimes referred to as the “nitroalkane anomaly”. Nitroalkane anomaly does not exist in the gas phase.

Table 13: Acid dissociation constants of mononitroalkanes.

Compound	Formula	pK_a	pK_a
Nitromethane	H_3CNO_2	10.18	10.24
Nitroethane	$H_3CCH_2NO_2$	8.46	8.6
1-Nitropropane	$H_3CCH_2CH_2NO_2$	8.98	—
2-Nitropropane	$(H_3C)_2CHNO_2$	7.67	—

1.4 Safety Properties of Mononitroalkanes

1.4.1 Drop Weight Impact Sensitivities of Mononitroalkanes

A method for prediction of impact sensitivity of nitroaliphatic compounds was based on some structural parameters of $C_aH_bN_cO_d$ explosives [77]. Three essential parameters would be needed in this scheme which contain $a + b/2 - d$ and the number of nitrogens as well as the number of $R-C(NO_2)_2-CH_2-$ structural parameters attached to oxygen of carboxylate functional groups where R is alkyl groups. The results were compared with experimental data and some empirical correlations. Predicted impact sensitivities for 58 explosives had a root mean square (rms) of deviation from experiment of 27 cm, which was considered good agreement with respect to less accurate values obtained with previous empirical models.

Drop weight impact sensitivities of 58 liquid explosives and melts of high explosives were summarized in [78]. Compounds that were solids at room temperature were heated to just above their melting points. This paper contained data on 4 nitroalkanes, 12 alkyl nitrate esters, 8 azidonitro compounds, 5 fluoronitro compounds and 14 nitramines. The data for individual nitro compounds were extracted from that paper and inserted in the hazard property tables of individual compounds (Table 14). The compound numbers in the first column of the table are the same as those used in Figure 2. The drop weight sensitivity was determined with a mass of 2.5 kg and the 50% heights in cm are listed in Table 14 and shown in Figure 2.

The drop weight sensitivity apparatus used for these tests differed from that used per American Society for Testing and Materials (ASTM) D2540 in that it deliberately subjected the samples to two consecutive impacts (whereas methods used in the US specifically prevent rebound and second impacts). The first impact causes cavitation and release of bubbles which sensitizes the explosive to the second impact. Linear correlations between the impact sensitivity of liquid high explosives and the maximum volumetric heat of explosion were obtained for several groups of

Table 14: Correlation between drop weight impact sensitivities of nitroalkanes, heat of formation, and heat of explosion.

No. Compound	H_{50}	T		ΔH_0		ρ	$Q_{\max}$	$\rho Q_{\max}$
	cm	K	°C	kJ/mol	kcal/mol	g/cm ³	kcal/g	kcal/cm ³

22 (NO ₂) ₃ CCH ₂ O(CH ₂) ₂ OCH ₂ C(NO ₂) ₃	7.5	308	35	-438	-104.6	1.60	1.647	2.64

Data source: [78]

Figure 2: Correlation between the sensitivity of aliphatic nitro compounds not containing azide and nitramine groups and their maximum volumetric heats of explosion (republished and modified from [78], with permission of © 2010 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

compounds, allowing one to predict the sensitivity of hitherto untested liquid high explosives based on physicochemical properties and elemental composition. Similar relationships were derived between drop weight sensitivity and onset of thermal decomposition. For aliphatic nitro compounds not containing azido or nitramino groups the correlation was (Figure 2)

$$H_{50} = [(30.0 \pm 2.8) - (10.6 \pm 1.3)\rho Q_{\max}]^2$$

The C—NO₂ bond dissociation energies of a series of model C-nitro compounds and 26 energetic C-nitro compounds have been calculated using density functional theory methods and compared to the measured drop weight impact sensitivity [79]. A linear relationship could be established. See also reference [80].

1.5 Toxic Properties of Mononitroalkanes

Toxicity properties of all mononitroalkanes are so similar that they can be discussed here together as a group [81]. The main difference between the different mononitroalkanes is their vapor pressure. Sections dealing with toxicity of individual mononitroalkanes are further down in this chapter, followed eventually by similar sections on polynitroalkanes.

Although aliphatic nitro compounds, aliphatic nitrates and aliphatic nitrites have several features in common (nitrogen–oxygen grouping, explosiveness, methemoglobin formation), there are significant differences in their toxic effects. Some of their attributes were summarized in a review paper [82]. The esters of nitric and nitrous acids, where nitrogen is linked to carbon through oxygen, are very similar in their pharmacological effects. Both produce methemoglobinemia and vascular dilatation with hypotension and headache. These effects are transient. None of the series has appreciable irritant properties. Pathological changes occur in animals only after high levels of exposure and are generally non-specific and reversible. Nitro compounds, like nitrates and nitrites, cause methemoglobinemia in animals. Heinz body formation parallels this activity within the series. Although some members are metabolized to nitrate and nitrite, there is no significant effect on blood pressure or respiration. In addition to respiratory tract injury, cellular damage may be observed in the liver and kidneys. Skin absorption is negligible except for the nitroolefins.

Guinea pigs, rabbits, monkeys, and a few rats were exposed to mononitroalkanes by oral administration, skin application, and inhalation [83]. No injury or death followed after any skin application. The weight of the molecule intensified and prolonged the toxic action. The most severe liver damage seen, with fatty infiltration, was caused by nitropropane. Severe central nervous system irritation followed inhalation of nitromethane. Loss of weight and a reduction in erythrocytes and hemoglobin were of uniform occurrence, but within normal limits and recovery was prompt. Lethal concentrations were far below narcotic concentrations, which cannot be used as a warning.

Summaries of toxicity information for nitromethane, nitroethane, 1-nitropropane, 2-nitropropane, trinitromethane and tetranitromethane were compiled in a government report [84]. Oral and inhalation toxicities and the degree of histological damage increase with increasing molecular weight of the compounds. Nitromethane and nitroethane (rat oral LD₅₀ > 1000 mg/kg) are less toxic than 1-nitropropane or 2-nitropropane (500–700 mg/kg), which in turn are less toxic than

tetranitromethane and trinitromethane (~300 mg/kg). The primary effects included histological liver damage and central nervous system depression, both atactic and narcotic changes, regardless of the route of administration or the duration of exposure. Vapor exposures also caused respiratory tract and conjunctival irritation and pulmonary edema. Symptoms of exposure in humans included headache, nausea, damage to the respiratory tract and liver damage. Most of human exposures to nitroparaffins resulting from occupational pursuits have been due to 2-nitropropane. The four higher molecular weight nitroparaffins (1-nitropropane and 2-nitropropane, tetranitromethane, and trinitromethane) additionally have been demonstrated to be methemoglobin poisons in animals. Chronic inhalation exposure to 2-nitropropane has been associated with the development of precancerous lesions in the liver and hepatocellular cancer in rats, and 2-nitropropane was a positive mutagen in the Ames Salmonella assay.

The more severe toxicity of polynitroalkanes such as trinitromethane or tetranitromethane is quite different from that of mononitroalkanes and will be dealt with in a separate section further down in this chapter (Section 5.5 and 6.10).

The Occupational Safety and Health Administration (OSHA) permissible exposure limits (PEL) total weight average (TWA) for nitromethane is 100 ppm and the OSHA PEL TWA for nitroethane is also 100 ppm. These values are quite high (safer) in comparison to nitrobenzene (OSHA PEL TWA = 1 ppm), which shows that the aliphatic nitro compounds are not nearly as toxic as their aromatic counterparts.

Nitromethane, nitroethane, and nitropropane are commonly used as solvents for lacquers, paints, and inks, and a large part of the general population may be exposed to vapors when doing painting. The synthesis of moisture-sensitive nitronium salts like nitronium perchlorate is best done in nitromethane as the solvent.

The hepatotoxic and mutagenic potentials of nitromethane, nitroethane, and 2-nitropropane were assessed biochemically and histopathologically in mice [85]. In male mice, plasma activities of the hepatic enzymes were significantly elevated 48, 72, and 96 h after i.p. administration of 9 mmol/kg 2-nitropropane, but not after administration of nitromethane or nitroethane. In female mice a dose of 6.7 mmol/kg of 2-nitropropane was sufficient to cause hepatotoxicity. The histopathological evaluation supported the biochemical results, and livers of mice that had received 2-nitropropane (9 mmol/kg) showed damage. Mutagenicity was tested in *Salmonella typhimurium* tester strains TA98, TA100, and TA102. Both 2-nitropropane and its anionic form, propane-2-nitronate, were mutagenic but the nitronate was the more powerful mutagen. Neither nitromethane, nitroethane nor their nitronates caused an increase in the number of revertant colonies over those seen in control plates. The results suggested that the primary nitroalkanes are much less hepatotoxic and mutagenic than 2-nitropropane.

1.6 Applications of Nitroalkanes

The list of industrial applications of nitroalkanes is very long, too long to include in this book. We are listing here only a few summaries on uses of nitroalkanes as energetic materials in propellants and explosives. A recent book on liquid explosives contains a chapter on nitro compounds as liquid explosives [86].

2 Nitromethanes

In methane 1–4 hydrogen atoms can be replaced by nitro groups, forming a family of progressively more oxygen-rich organic oxidizers.

2.1 Comparative Evaluation of Physical Properties of Nitromethanes as a Group

Table 15 is a summary of physical properties and acidity constants of nitromethanes. Due to the electrophilic nature of the nitro group, replacing more and more hydrogen atoms in methane by nitro groups causes the remaining hydrogens to become more and more acidic, to the point that trinitromethane is a weak acid and forms salts with many metals and with ammonium or hydrazinium cations; however, the increase in acidity, as measured by pK values in various solvent systems, is not proportional to the number of nitro groups present, a dampening effect being observed upon substitution [87, 88].

2.2 Comparative Evaluation of Chemical Properties of Nitromethanes as a Group

A computational investigation of the nitro, nitrite, and *aci*-form isomers and the isomerization reactions of mononitromethane, dinitromethane, trinitromethane, and tetranitromethane showed that the isomerization displacement of NO₂ by ONO groups was surprisingly thermodynamically favored for dinitromethane, trinitromethane, and tetranitromethane [89]. The molecular stability decreased and the isomerization became easier by increasing the number of nitro groups. The largest attraction among substitutes took place through the central carbon atom in C(ONO)₄ and led to a higher stability than that of the C(NO₂)₄ isomer.

Table 15: Effect of progressive substitution of hydrogen in methane by nitro groups on physical properties.

Compound	Formula	Melting point		Boiling point		Acidity, pK	
		K	°C	K	°C	Niemeyer [87]	Rezende [76]
Methane	CH ₄	90.67	−182.48	111.7	−161.5	—	—
Nitromethane	CH ₃ NO ₂	244.6 ± 0.05	−28.55 ± 0.05	374.1 ± 0.8	101 ± 0.8	10.24	10.24
Dinitromethane	CH ₂ (NO ₂) ₂			Decomposition		3.57	3.63
Trinitromethane	CH(NO ₂) ₃	292	18.9	Decomposition		0.17	0.06
Tetranitromethane	C(NO ₂) ₄	287.05 ± 0.2	13.9 ± 0.2	399.2	126.1	—	—

3 Nitromethane

Nitromethane, mononitromethane, H_3CNO_2 , NM, Chemical Abstracts Service (CAS) RN [75-52-5], is the lowest member of the family of nitro compounds, and one of the most important ones at the same time.

3.1 Production of Nitromethane

The four lower mononitroparaffins (nitromethane, nitroethane, 1-nitropropane, and 2-nitropropane) are produced on a large industrial scale by oxidizing an excess of vapor-phase propane with nitric acid at a temperature range of 643–723 K (370–450 °C) and pressure of 0.8–1.2 MPa (8–12 atmospheres). This reactant combination sounds more like a rocket propellant and indeed explosions can occur during this process. Approximately 40% of the nitric acid is converted to nitroparaffins; the remainder acts as an oxidizing agent to produce unwanted oxygenated by-products and is reduced to nitric oxide. The products are 48.2 mol-% 2-nitropropane, 22.0 mol-% nitromethane, 16.6 mol-% nitroethane, and 13.2 mol-% 1-nitropropane. Industrial grades of nitroethane contain these byproducts as contaminants.

Commercial nitromethane that needs to be purified to determine accurate physical properties can be purified by a sequence of aqueous solution washings of sodium bicarbonate, sodium bisulfite, and sulfuric acid, followed by two fractionated distillations, one at ambient pressure and one at reduced pressure, on long columns with high reflux ratios and discarding the early fractions [90]. It is difficult to separate the azeotrope formed between nitromethane and water to obtain an anhydrous product with better than 99.9 mol-% nitromethane.

3.2 Physical Properties of Nitromethane

The physical properties of nitromethane are well characterized and the data are fairly accurate. Several summaries of the physical and chemical properties of nitromethane have been published as summarized in Table 16.

Very good summaries of literature data including physical properties, thermodynamic properties and kinetics of decomposition were compiled specifically to collect information for the intended utilization of nitromethane as a rocket propellant [93, 99]. Standard textbooks and encyclopedias on explosives contain chapters on nitromethane [100, 101].

3.2.1 Freezing Point, Boiling Point, and Phase Diagrams of Nitromethane and Nitromethane Mixtures

Studying the thermodynamic melting point of crystalline nitromethane by molecular dynamics simulation computations, the melting mechanism of superheated crystalline nitromethane, and the physical properties of crystalline and glassy nitromethane showed that the maximum superheating and glass transition temperatures of nitromethane were 316 and 160 K, respectively, for heating and cooling rates of 8.9×10^9 K/s [102]. Using the hysteresis method and by taking the glass transition temperature as the supercooling temperature, a value of 251 K for the thermodynamic melting point was in excellent agreement with the two-phase result of 255.5 K and measured value of 244.73 K.

The boiling point of the azeotrope formed between nitromethane and water is 356.74 K (83.59°C). The azeotrope distillate contains 76.4 mass-% nitromethane. A phase diagram that includes triple point and critical point was constructed from literature data (Figure 3).

During production of nitroalkanes, often mixtures of nitromethane and nitroethane are obtained that need to be separated by fractionated distillation. In other applications, nitroethane is added to nitromethane on purpose to reduce its sensitivity and the vapor and liquid composition of binary mixtures must be known. In either case, it will be necessary to know the vapor phase diagram of binary mixtures of nitromethane and nitroethane [103].

3.2.2 Density of Nitromethane and Nitromethane Mixtures

Density data from different sources, not always very consistent with each other, are collected in Table 17.

Table 17: Density of nitromethane.

The density of liquid nitromethane between 298 and 473 K (25 and 200 °C) can be calculated from the following equation [106]:

$$\rho = 1.1615 - 1.1952 \times 10^{-3}t - 1.553 \times 10^{-6}t^2$$

where ρ is the density in g/cm³ and t is the temperature in °C.

Density data from several sources have been examined and curve-fitted to result in the equation published by the Design Institute for Physical Properties (DIPPR) database, which is good for the temperature range 245–588 K:

$$\rho = \frac{A}{B[1 + (1 - \frac{T}{C})^D]}$$

where ρ is the density in g/cm³, T is the temperature in kelvin and the constants A through D are A = 1.3793, B = 0.23918, C = 588.15, and D = 0.29030.

A number of studies reported the physical properties of nitromethane and alcohol mixtures including miscibility. Deuteration both in the OH group of alcohol and/or the methyl group of nitromethane increased (widened) the domain of the limited miscibility of nitromethane and alcohol mixtures [107].

When measuring the solubility of nitromethane and water in each other, it appeared that deuteration in the OH group of water increased the region of limited mis-

cibility, while deuteration in the methyl group of nitromethane decreased this region [108]. Excess volumes, densities, and viscosities of binary mixtures of aliphatic alcohols (C_1 – C_4) with nitromethane were measured [109]. Temperature dependence of densities and speeds of sound of nitromethane and butanol isomers were measured in the range 288–308 K [110]. Although no application to propulsion was given as a reason for doing this work, the inclusion of butanol in these studies is interesting since it had previously been shown to act as a desensitizer. The coefficient of thermal expansion of nitromethane between 278 and 313 K (5 and 40 °C) is $1.24 \times 10^{-3} \text{ }^\circ\text{C}^{-1}$ [111].

3.2.3 Compressibility, Velocity of Sound, and Equation of State of Nitromethane

The compressibility of nitromethane is $7.26 \times 10^{-10} \text{ m}^2/\text{N}$ ($7.36 \times 10^{-5} \text{ atm}^{-1}$) [112]. The velocity of sound in liquid nitromethane at 298 K (25 °C) is $1.30 \pm 0.05 \text{ mm}/\mu\text{s}$ [111].

The pressure and temperature effects on the structural properties of denser liquid nitromethane have been examined computationally in terms of some characteristic pair radial distribution functions [113]. With potential functions including the harmonic intramolecular interaction and Lennard-Jones plus columbic intermolecular interactions, classical dynamic simulations were performed for liquid nitromethane. Constant pressure-temperature and constant volume-temperature simulations in the range of pressure from 101 kPa to 24.3 GPa and the range of temperature from 300 to 1300 K. The classical molecular dynamics simulation gave results close to experimental results, but the calculated Hugoniot pressure was too high compared to experimental results. The computed shock temperature was lower than the experimental one. Analysis of the pair correlation functions revealed that the short-range repulsion becomes very important at high density.

A reliable equation of state (EOS) for unreacted liquid nitromethane is needed for computations of detonation velocity and detonation pressure and to predict the behavior of liquid nitromethane under conditions of very high pressure that precede the detonation front. There are several equations of state for nitromethane described in the literature.

One example of an EOS predicts the hot spot size required for propagation of detonations in nitromethane [114]. An early method for developing an EOS for nitromethane was based on extended integration schemes [115]. The energy-pressure-volume EOS was derived from a combination of the known variation of energy with temperature along the atmospheric pressure isobar and the Hugoniot jump relations. The energy-entropy-volume equation was generated by a numerical integration of the coupled differential equations governing the entropy and temperature variation along a Hugoniot curve.

The EOS proposed by Winey et al. [116] was based on a method where the specific heat C_v , the isothermal bulk modulus B_T and the coefficient of thermal pressure $(\partial P/\partial T)_V$ were modeled as functions of temperature and volume using experimental

data. In order to test this EOS, temperature measurements using time-resolved Raman spectroscopy were obtained from nitromethane subjected to stepwise loading. Calculations using the new EOS showed good agreement with the measured temperatures. Comparison with previous EOS models showed that simplifying assumptions, such as holding $(\partial P/\partial T)_V$ or γ_V constant, would lead to significant inaccuracies in temperature predictions for shocked nitromethane.

A perturbation calculational technique was used to predict the thermodynamic properties of nitromethane at high pressures [117]. The intermolecular interaction can be described by a spherically symmetric, exponential-6 potential and an angular dependent, multi-polar contribution. Isothermal compression and the shock Hugoniot for nitromethane can be characterized by the theory. Molecular dynamics calculations, with the intermolecular forces constructed from interatomic interactions, can describe the experimental observations under consideration. There was a considerable difference in the predicted shock temperatures from the two methods.

An EOS for unreacted nitromethane provided accurate temperatures required to support a temperature-dependent reaction rate within a reactive flow model [118]. A quasi-harmonic form was normalized to shock wave data, but with a more rigorous treatment of thermal modes. A reactive flow model that included temperature as well as mechanical state was used to investigate shock initiation in nitromethane. Temperatures predicted by the model for various off-Hugoniot states in reactive configurations showed reasonable agreement with data from experimental measurements.

A new molecular force field for nitromethane obtained by means of Monte Carlo molecular simulations was proposed that lead to a good description of shock properties [119]. Results of calculated properties of shocked nitromethane are in good agreement with experimental shock Hugoniot data, including temperature measurements of second shock Hugoniot.

The Hugoniot curve of inert (non-reactive) nitromethane can be computed using Monte Carlo simulations with a modified version of an adaptative equation of state and intermolecular potential data [120]. Molecular dynamic simulations of nitromethane decomposition have been performed using a reactive potential, allowing the calculation of kinetic rate constants and activation energies.

Another EOS of unreactive shocked liquid nitromethane was not based on extended integration schemes but the complete EOS was computed by microscopic calculations with molecular simulations [121]. Measured shock temperatures and second shock temperatures were accurately reproduced which indicated the quality of the equation.

3.2.4 Critical Point Properties of Nitromethane

Under conditions of the critical point, nitromethane is likely to explode prematurely before any measurements can be taken. The critical point data were derived from other physical properties [122–124]:

$$T_{\text{crit.}} 588 \text{ K} = 315^\circ\text{C}$$

$$P_{\text{crit.}} 6.28 \pm 0.1 \text{ MPa} = 62.2 \pm 1 \text{ atm} = 63.10 \text{ bar}$$

$$\rho_{\text{crit.}} 0.352 \pm 0.004 \text{ g/cm}^3 = 5.77 \text{ mol/L}$$

3.2.5 Vapor Pressure of Nitromethane

The vapor pressures of nitromethane as a function of temperature are listed in Table 18 in comparison to that of nitroethane. The vapor pressure of nitromethane can be calculated from the following equations:

The first equation in the form of an Antoine equation based on 15 data points taken between 328 and 409 K (55 and 136 °C) gives the vapor pressure as follows [95]:

$$\log p_v = 7.28050 - \frac{1446.186}{t + 227.515}$$

where p_v is the vapor pressure in mm Hg and t is the temperature in °C. From another source, an Antoine type equation can give the vapor pressure very accurately [11]:

$$\log p_v = 7.274170 - \frac{1441.610}{t + 226.939}$$

Table 18: Vapor pressure of nitromethane and nitroethane.

Temperature		Vapor pressure	
K	°C	Nitromethane	Nitroethane
		mm Hg	mm Hg
283	10	16.12	8.52
293	20	27.89	15.65
298	25	36.26	20.89
303	30	46.67	27.41
313	40	75.21	46.20
323	50	117.1	74.55
333	60	178.2	113.2
343	70	262.7	173.9
353	80	377.7	254.2
363	90	530.2	361.1
373	100	730.4	499.4
383	110		676.6

Data source: [16]

where p_v is the vapor pressure in mm Hg and t is the temperature in °C. Taking the McCullough et al. [95] data and converting them to Antoine equation parameters for the temperature range 329–409 K results in

$$\log_{10}(P) = 4.40542 - [1446.196/(T - 45.633)]$$

where P is the vapor pressure in bar and T is the temperature in kelvin. The normal boiling point from this equation is 374.35 K (101.19 °C).

Another equation based on measurements between 403 and 473 K (130 and 200 °C) gives the vapor pressure in units of atmospheres [106]:

$$\log p = 10.8210 - 3905.39/(t + 260)$$

where p is the vapor pressure in atm and t is the temperature in °C. Taking the Berman and West [106] data and converting them to Antoine equation parameters for the temperature range 405–476 K results in

$$\log_{10}(P) = 4.11350 - [1229.574/(T - 76.221)]$$

where P is the vapor pressure in bar and T is the temperature in kelvin. The same data were also expressed in the form of a Cox equation:

$$\log p_v = A \left(1 - \frac{374.347}{T} \right)$$

$$\log A = 0.845118 - 6.1497 \times 10^{-4} T + 6.0541 \times 10^{-7} T^2$$

where p_v is the vapor pressure in atm and T is the temperature in kelvin. This latter equation allows some extrapolation beyond the range of measured data.

The vapor density of nitromethane vapor was measured by the Dumas method between 380 and 439.6 K (107 and 166.5 °C) [125]. The measured densities were 1–2% higher than values calculated from the ideal gas law. In spite of its high dipole moment (3.44 D), nitromethane molecules are not significantly associated in the vapor phase.

The DIPPR database offered the following equation which was the result of combining and curve-fitting data from several sources:

$$P = e^{\left(A + \frac{B}{T} + C \ln T + DT^E \right)}$$

where P is the pressure in Pa and T is the temperature in kelvin. The coefficients A, B, C, D, and E are listed in Table 19. See also reference [94].

Table 19: Coefficients for nitromethane vapor pressure correlation.

Temperature, K	A	B	C	D	E
244–588	8.7411 E01	–7.1332 E03	–9.7786	7.9061 E–06	2.0000

Data source: DIPPR

3.2.6 Viscosity of Liquid Nitromethane

The viscosity of liquid nitromethane is listed in Table 20.

Table 20: Viscosity of liquid nitromethane.

Temperature		Absolute viscosity	Data source	Ref.
K	°C	cPs		
288	15	0.694	Makovky and Lenji 1958	[93]
298	25	0.632		
303	30	0.595	Thompson, Coleman, and Helm 1954	[90]
293	20	0.646		
298	25	0.608		
303	30	0.574	Bellinger et al. 1948a	[105]
283	10	0.748		
298	25	0.625		
313	40	0.533		

Nitromethane that has been gelled to reduce the leakage potential, prevent sloshing or to suspend solid particulate additives has a higher viscosity, and its rheological behavior is different from that of ungelled nitromethane [126]. Its viscosity determines the droplet size and combustion rate when sprayed into a combustion chamber [127].

3.2.7 Surface Tension of Nitromethane

Literature data for the surface tension of liquid nitromethane are listed in Table 21.

Table 21: Surface tension of nitromethane.

Temperature		Surface tension		Source	Ref.
K	°C	dyn/cm	N/m		
288	15	37.74	0.0377	Makovky and Lenji 1958	[93]
298	25	36.97	0.0370		
303	30	35.48	0.0355	Thompson, Coleman, and Helm 1954	[90]
293	20	37.5	0.0375		
298	25	36.7	0.0367		
303	30	35.9	0.0359		

Note: $10^5 \text{ dyn} = 1 \text{ N}$; $1 \text{ dyn/cm} = 10^{-5} \text{ N/cm} = 10^{-3} \text{ N/m}$

3.2.8 Thermal Conductivity of Nitromethane

The thermal conductivity of liquid nitromethane is $0.216 \text{ W m}^{-1} \text{ K}^{-1}$ ($5.17 \times 10^{-4} \text{ cal cm}^{-1} \text{ }^{\circ}\text{C}^{-1} \text{ s}^{-1}$) [112].

3.2.9 Optical Properties of Nitromethane

3.2.9.1 Infrared Spectra of Nitromethane

Infrared spectra of nitromethane are useful to verify the purity of nitromethane samples, to detect leaked nitromethane in the air surrounding storage facilities and to track the rate of decomposition of nitromethane in a monopropellant reactor. The IR spectrum of nitromethane vapor is shown in Figure 4.

The gas-phase infrared spectra of nitromethane, the various skeletal modes of vibration, and the vibrations of the methyl group with dipole changes parallel to the carbon-nitrogen have vibration-rotation band contours, which are of the expected type as calculated from the moments of inertia for overall rotation of the molecule [129]. The perpendicular vibrations of the methyl groups all had complex contours, and in a number of cases widely spaced fine structure lines were present. These could only be accounted for in terms of internal rotation degrees of freedom. This was expected because in classical terms the internal rotation frequencies modulate the oscillating vibrational dipole moment of these (and only these) methyl vibrations. In quantum-mechanical terms this leads to additional transitions involving changes in the quantum number for internal rotation. Analyses of the bands in this manner lead to information about the band origins and to reasonable values for the Coriolis coupling constants of the degenerate vibrations.

IR spectroscopic data obtained for binary and ternary liquid mixtures showed that nitromethane may act as proton donor for weak hydrogen bonds with appropriate

Figure 4: Infrared spectrum of nitromethane vapor (reproduced and modified with permission from [128])

acceptor groups in solvents [130]. At low concentrations of nitromethane in CCl_4 an equilibrium between monomer molecules and predominantly anti-parallel oriented ($\rightleftharpoons$) dimers may be inferred from IR spectroscopic and static dielectric studies. The IR and Raman spectroscopic data provided conclusive evidence for the preservation of a predominantly anti-parallel orientation at high nitromethane concentrations and even in pure liquid nitromethane. Similar observations were made with Raman and nuclear magnetic resonance (NMR) spectra, showing that intermolecular self-association slows the spinning motion of nitromethane in the liquid phase [131].

The infrared spectra of normal and deuterated nitromethane isolated in a nitrogen matrix were recorded from 4000 to 250 cm^{-1} [132]. Peaks have been assigned to monomer and dimer species by varying the concentration of nitromethane in the matrix. The frequencies of the monomer have been used in a normal coordinate analysis and the force constants agreed well with those of the gas phase. The Cartesian displacements of the atoms for each normal mode showed that for the “ NO_2 anti-symmetric vibration” there was considerably more motion of the hydrogen atoms. The results will make it possible to estimate the moments of inertia of the dimer and force constants for the pair necessary for assessing partition functions for dimer formation under all conditions of temperature and pressure.

The vibrational relaxation processes of totally symmetric ν_1 (CH stretching and ν_5 NO_2 bending) motions of liquid nitromethane have been studied as a function of temperature and concentration in CD_3NO_2 and CCl_4 solutions [133]. The experimental vibrational correlation functions of these two modes have shown that relaxation is collision-assisted and suitable for modeling with a stochastic theory.

Answers to the question about the barrier height for the internal rotation of the methyl group around the C—N axis in nitromethane have been sought by many studies, either using experimental procedures or by means of theoretical approaches. From different literature data one can deduce that the potential surface and consequently the barrier height for the internal rotation is dependent essentially on the molecular physical state. In the gas phase, where molecular interactions are almost absent at atmospheric pressure and room temperature, it has been reported that this barrier is nearly non-existent, being ca. 25 J/mol (6 cal/mol) for the light nitromethane, and 21.7 J/mol (5.2 cal/mol) in the case of d_3 -nitromethane. Therefore, the rotation of the methyl group around the C—N single bond is quasi free, and should be associated with a torsional motion at very low frequency [134].

Infrared and Raman spectroscopy has been used to study totally symmetric ν_4 and ν_5 motions of CH_3NO_2 and CD_3NO_2 isotopomers, in order to ascertain the nature of the low-frequency features appearing in these bands. A study of the gaseous phase IR spectra and of the temperature effects, carried out under high-resolution conditions on both liquid and gaseous molecules, showed that these features are connected to the effects of conformational population and not to hot band transitions, as it had been previously reported [135].

The methyl C—H stretching overtone spectra of gaseous nitromethane have been recorded with Fourier transform infrared (FTIR) spectroscopy in the $\Delta\nu_{\text{CH}} = 1$ –4 regions and by intracavity laser photoacoustic spectroscopy in the $\Delta\nu_{\text{CH}} = 5$ and 6 regions [136]. They all exhibited a complex structure with, at $\Delta\nu_{\text{CH}} = 1$ and 2, a characteristic asymmetric top vibration-rotation profile, which vanished as vibrational energy increased. The perpendicular stretching vibrations exhibited a widely spaced fine structure profile resulting from a Coriolis coupling induced by the methyl internal rotation. These excited spectra have been analyzed with a theoretical model, which in the adiabatic approximation, took into account the coupling of the anharmonic C—H stretch vibrations with the quasi-free internal rotation of the methyl group and with isoenergetic combination states involving methyl bending modes. These calculations successfully described the relative intensity and frequency of each peak within a given overtone.

Non-equilibrium molecular dynamic simulations were used to study vibrational energy relaxation in liquid nitromethane after excitation of the C—H stretching vibrations [137]. The simulated liquid was assumed to consist of a mixture of excited and unexcited molecules, where the unexcited molecules were used to monitor excitation of the bath upon vibrational relaxation of the excited molecules. The results were in qualitative agreement with experimental measurements in liquid nitromethane after mid-IR excitation in the C—H stretching region. The simulation results indicated that the excited C—H stretching vibrations deposit energy predominantly into the remaining vibrations in the molecules. These vibrations relax at different rates, resulting in a multi-stage vibrational cooling process for nitromethane, in agreement with experimental results.

The effects of pressure on the vibrational spectra of crystalline nitromethane have been studied by computing normal mode frequencies, eigenvectors, and classical power spectra at several hydrostatic pressures between 0 and 27.3 GPa [138]. The purpose of the study was to determine the limits within which the force field, and classical mechanics more generally, accurately represented the pressure effects observed experimentally. The results exhibited good agreement between the calculated normal mode frequencies (and especially their pressure-dependent shifts) and those obtained in experimental and theoretical studies. Comparisons of the pressure dependencies near room temperature to experimental pressure-dependent IR spectra for particular vibrational modes yielded, in the case of the C—N stretch, a CH_3 deformation and the NO_2 asymmetric stretch.

3.2.9.2 Raman Spectra of Nitromethane

The frequency shifts of the C—N stretching mode of shock-compressed nitromethane have been measured using coherent anti-Stokes Raman scattering [139]. Shock pressures up to 11 GPa were achieved using a two-stage light gas gun. The frequency shifted Raman signal was generated using single-pulse Nd:YAG and broadband type lasers.

Raman and coherent anti-Stokes Raman spectroscopy and transient optical Kerr effect measurements were performed to study rotational and vibrational relaxations in the totally symmetric ν_4 mode in CH_3NO_2 [140].

Time-resolved Raman spectra of liquid nitromethane shocked to 140 kbar peak pressure showed that the C—N stretch (917 cm^{-1}), CH_3 stretch (2968 cm^{-1}), and the NO_2 stretch/ CH_3 bend ($1400/1377\text{ cm}^{-1}$) vibrations would all harden when peak pressure was obtained [141]. Upon unloading from 140 kbar, the C—N stretch vibration reverted back without any signs of irreversible change. The CH_3 stretching mode exhibited the largest increase with peak pressure. The observed frequency hardening and band broadening indicated strong intermolecular interactions at these shock pressures. When shocked by stepwise loading to 14.2 GPa, changes in the nitromethane vibrational modes and the spectral background were characteristic of the onset of reaction [142].

Polarization-sensitive coherent anti-Stokes Raman scattering spectroscopy was applied for detailed analyses of vibrational resonances of neat liquid nitromethane in the spectral range $900\text{--}1500\text{ cm}^{-1}$ [143], and showed that the main totally symmetric band ν_4 at 917 cm^{-1} and its observed asymmetry on the lower wave number side (previously assigned to hot bands) are in fact two different bands. Raman spectra indicated that at pressures above 4 GPa, the methyl group in nitromethane is locked and rotated about 45 from its position at lower pressures [144].

The phase transitions and the decomposition limits of nitromethane have been examined by Raman scattering in the pressure and temperature range of $0\text{--}25\text{ GPa}$ and $293\text{--}423\text{ K}$ and by analysis of the evolution of different Raman modes [145, 146]. Three new solid phases of nitromethane called III, IV, V have been detected [147]. A first chemical transformation was observed by the disappearance of nitromethane Raman modes and by the irreversible formation of a transparent solid called compound I. A second chemical transformation at higher temperature than the first one, was observed by the sudden darkening of the sample. A comparison of the Raman spectrum of nitromethane- h_3 with new high pressure Raman spectroscopic results for isotope-labeled nitromethane- d_3 and nitroethane allowed one to characterize the physico-chemical behavior of these three compounds in relation to their detonation properties [148].

A detailed Raman spectroscopic study of nitromethane in the temperature interval from room temperature to 15 K showed that the crystal structure was stable from 15 to 242 K [149]. In the interval $243\text{--}244\text{ K}$ a new phase was observed before the transition into the liquid state took place. These observations were supported by differential scanning calorimetry (DSC) measurements which indicated the existence of an intermediate phase between the stable crystal form and the liquid phase. The activation energy for the internal rotation of the methyl group was $25 \pm 1\text{ meV}$, which was in good agreement with the energy difference between the ground energy level and the barrier ridge as determined by previous neutron and Raman scattering experiments.

Anti-Stokes Raman scattering was used to monitor vibrational energy redistribution in the ambient temperature normal nitromethane and perdeuterated nitromethane after ultrafast IR excitation of either the symmetric or asymmetric C–H- or C–D-stretch transitions [150]. The instantaneous populations of most of the 15 nitromethane vibrations were determined, and a global fitting procedure with a master equation was used to fit all the data. The pump IR pulses excited not only C–H and C–D stretches but also certain combinations of bending and nitro stretching fundamentals. The coupled vibrations that comprise the initial state were revealed via the instantaneous rise of the anti-Stokes transients associated with each vibrational fundamental.

3.2.9.3 Ultraviolet Spectra of Nitromethane

The UV spectrum of nitromethane is shown in Figure 5. The UV absorption spectrum of nitromethane was measured under various conditions [151]. Besides the weak band at 270 m μ , a strong band, which may be regarded as due to the longest wavelength $\pi \rightarrow \pi^*$ transition band, was observed at 198 m μ in the gaseous state. When the absorption spectrum of nitromethane was measured in aqueous solutions with several different pH values, a strong band was observed at 233 m μ . From the fact that the pK_a value evaluated on the basis of the pH dependence of the absorption intensity was equal to that obtained electrometrically, it was concluded that the 233 m μ band is to be ascribed to the nitromethyl anion ($^-\text{CH}_2\text{—NO}_2$). The π -electron structure of the anion was studied theoretically by taking into account configuration interactions in terms of the ground state, charge transfer, and locally excited configurations. It was shown that the 233 m μ band of the anion may be interpreted as an intramolecular charge-transfer absorption involving a large electron transfer from $^-\text{CH}_2$ toward NO_2 .

Figure 5: UV spectrum of nitromethane (reproduced and modified with permission from [91], Grammaticakis 1950, retrieved 7 June 2021)

The electron structures, electron spectra, and the self-consistent molecular orbitals and energies of the π -electron system have been calculated by a semiempirical method [152]; however, for the non-bonding σ -electron system Hückel-type molecular orbitals were used. The non-bonding 2p oxygen orbitals of nitromethane were very slightly modified by mixing with the σ -electron system. The calculated transition energies of nitromethane were in reasonable agreement with experimental results.

Polarized emission spectra from photodissociating nitromethane excited at 200 and 218 nm showed a strong progression in the —NO_2 symmetric stretch and at 200 nm a weak progression in the —NO_2 symmetric stretch in combination with one quantum in the C—N stretch [153]. The analysis of the photon angular distribution measurements and consideration of the absorption spectrum indicated that the time scale of the dissociation was too fast for molecular rotation to contribute significantly to the observed reduction in anisotropy. The analysis suggested a reassignment of the minor dissociation channel, first evidenced in photofragment velocity analysis experiments, which detected a pathway producing slow CH_3 fragments, to the near threshold dissociation channel leading to $\text{CH}_3 + \text{NO}_2$.

Time-resolved UV-visible absorption spectroscopy was used to examine the chemical decomposition in neat liquid nitromethane subjected to stepwise shock loading to 19 GPa [154, 155]. Up to a peak pressure (temperature) of 13.8 GPa (854 K), no sign of chemical reaction was observed in the $n\pi^*$ absorption band centered at 270 nm.

3.2.9.4 Microwave Spectra of Nitromethane

The microwave spectra of nitromethane and five isotopic species have been measured to determine the molecular structure [156]. Ground-state moments of inertia for the $m = 0$ internal rotation state gave the following structure: C—N = 1.489 Å, N—O = 1.224 Å, $\angle \text{ONO} = 125.3^\circ$, and $\angle \text{NCH} = 107.2^\circ$. Nuclear spin weightings for various $|K - m|$ states, derived using non-rigid group theory, have been confirmed by relative intensity measurements in the microwave spectra. The structure and bonding of nitromethane was compared to that of some related molecules. The structure of the nitro group in nitromethane was shown to fit a series of NO_2 compounds where the parameters varied according to the electronegativity of the attached R grouping.

The $J = 1$ to $J = 2$ and $J = 2$ to $J = 3$ transitions for CH_3NO_2 and CD_3NO_2 have been assigned for several internal rotational states [157]. The best values of the rotational constants B and C were found to be 10542.7 and 5876.7 Mc/s for CH_3NO_2 and 8697.1 and 5254.3 Mc/s for CD_3NO_2 . The rotational constant for the NO_2 group about the symmetry axis is 13277.5 Mc/s. The dipole moment of CH_3NO_2 is 3.46 ± 0.02 Debye units. Other sources report 3.44 D. See also [158–160].

3.2.9.5 Index of Refraction of Nitromethane

The index of refraction of nitromethane at different temperatures is listed in Table 22.

Table 22: Index of refraction n_D of nitromethane.

Temperature		Index of refraction n_D	References
K	°C		
293	20	1.38188	[11]
293	20	1.38197	[90]
298	25	1.37963	[90]
298	25	1.3818	[16]
298	25	1.37964	[11]
303	30	1.37738	[11]
298	25	1.37970	[104]
293	20	1.3821	[103]

Additional data on the index of refraction of nitromethane at three different temperatures and seven different wavelengths are listed in Table 23.

Table 23: Index of refraction of purified nitromethane at different wavelengths.

Temperature		Wavelength, Å

Data source: [90]

The index of refraction of shock-compressed liquid nitromethane has been determined from 7.5 to 9.5 GPa under the condition of 1-dimensional compression in the liquid [161]. Diagnostic information obtained by means of streak camera photography and velocity interferometry was compared with previously obtained EOS information in order to evaluate the refractive index of the shocked liquid prior to the onset of chemical decomposition.

3.2.10 Electrical Properties of Nitromethane

The dipole moment of liquid CH_3NO_2 is 3.46 ± 0.02 Debye units [157]. Other sources [92] reported a dipole moment of 3.56 D. Other sources gave a dipole moment of 3.17 D.

The relative permittivity (dielectric constant), ϵ/ϵ_0 is 35.94 [92]. These numbers can be compared to the dielectric constants for higher nitroalkanes, 3.19 D for nitroethane, 3.4 D for 2-nitropropane and 3.29 D for 1-nitrobutane.

The values of the dielectric constants of dilute solutions of nitromethane in heptane were used to calculate the dipole moments of the solute molecules, but the values thus calculated were considerably lower than those previously obtained in the gaseous state [104]. Measurements of the dielectric constant of pure liquid and solid nitromethane failed to show the existence of molecular rotation in the solid state. At 70 kHz and 183–244 K (–90 to –29 °C) (just below the melting point, 244.5 K = –28.6 °C), the dielectric constant of solid nitromethane increased from 3.39 to 3.93. The dielectric constant of liquid nitromethane between 246.4 and 300.5 K (–26.7 and +27.4 °C) decreased from 44.46 to 34.48. The dipole moment of nitromethane vapor at 298 K was 3.28 D (calculated) or 3.42 D (observed).

The electrical conductivity of dry nitromethane is $6.56 \times 10^{-7} \Omega^{-1} \text{cm}^{-1}$. Resistivity, relative static dielectric permeability, and electrical polarization relaxation time were measured for nitromethane that was compressed by a shock wave to pressures between 0.79 and 8.69 GPa [162]. Over this pressure range, the delay time for initiation of detonation exceeded 1 μs , which was sufficient time to measure properties of the unreacted material. The viscosity of nitromethane at high dynamic pressures was computed from other data.

3.2.11 Magnetic Properties of Nitromethane

Chemical shifts of protons in nitroalkanes at 60 MHz are affected by the inductive effect of the nitro group and the diamagnetic anisotropy of the C–C bond in nitroalkanes with $C_{n>1}$ [163]. The inductive effect was shown to extend as far as the fourth carbon atom in an *n*-alkyl chain. The ^1H chemical shifts in the series CH_4 , CH_3NO_2 , $\text{CH}_2(\text{NO}_2)_2$, $\text{CH}(\text{NO}_2)_3$ decreased in the order 9.767, 5.72, 3.90, 2.48 ppm. NMR studies of the deuteron and proton relaxation rates of liquid nitromethane at various temperatures indicated that the spin-rotation interaction contribution and the spin-rotation relaxation times provided evidence for large spin-rotation effects due to the internal rotation of the methyl group [164, 165].

3.2.12 Thermodynamic Properties of Nitromethane

Because nitromethane has been used as a model substance for study of other explosives containing nitro groups, its thermodynamic properties have been thoroughly investigated both experimentally and theoretically/computationally, not always with full agreement between the different sets of data.

Most of the thermodynamic data for nitromethane are for the compound in the liquid state at room temperature and sea level atmospheric pressure; however, in the detonation shock front, nitromethane is highly compressed and its thermodynamic properties are different from those at normal pressure.

A method was suggested for calculating thermodynamic parameters of shock-compressed nitromethane, for which isentropic curves cannot be constructed due to the lack of appropriate initial data for entropy [166]. The method was based on the fact that in the space where dependences of the wave velocity, pressure, and internal energy on mass velocity are determined for each space point within a known set of initial thermodynamic quantities by shock-wave experiments without breaks and fractures, all the thermodynamic parameters of state can be uniquely determined without any additional information. The Grüneisen parameter and velocity of sound were calculated by differentiating a family of shock adiabats obtained for different initial temperatures.

3.2.12.1 Heat Capacity of Nitromethane

Heat capacity data for liquid nitromethane are listed in Table 24. The specific heat of nitromethane was determined using an adiabatic technique in a glass calorimeter at temperatures near 311, 344, and 372 K (100, 160, and 210 °F) [167]. The heat capacity of saturated liquid nitromethane (under its own vapor pressure) in the temperature range from 308–473 K (35–200 °C) can be expressed by the equation

$$C_p = 104.4 + 6.381 \times 10^{-2}t + 3.175 \times 10^{-6}t^2 - 8.131 \times 10^{-7}t^3 + 4.073 \times 10^{-9}t^4$$

where C_p is the heat capacity in $\text{J mol}^{-1} \text{K}^{-1}$ and t is the temperature in °C [168]. The same data for liquid nitromethane for a temperature range from 244 to 473 K (–29 to +200 °C) can be expressed by a simpler second-order polynomial with a 3% error probability:

$$C_p = 1.1627 \times 10^5 - 135.3T + 0.345T^2$$

Table 24: Heat capacity of nitromethane.

Physical state	Temperature		Heat capacity				Source	References
	K	°C	$\text{J g}^{-1} \text{K}^{-1}$	$\text{cal g}^{-1} \text{°C}^{-1}$	$\text{J mol}^{-1} \text{K}^{-1}$	$\text{cal mol}^{-1} \text{°C}^{-1}$		
Liquid	290.15	17	1.7238	0.412			Armstrong 1960	[169]
Liquid	294.25	21.1	1.7071	0.408

Vapor	298.15	25	0.939	0.224	57.32	13.70	McCullough et al. 1954	[95]

$$M = 61.040 \text{ g/mol} = 16.3827 \text{ mol/kg}$$

where C_p is the heat capacity in $\text{J mol}^{-1} \text{K}^{-1}$ and T is the temperature in kelvin. The vapor heat capacity of nitromethane in the range 363–523 K (90–250 °C) can be calculated from the following equation [95]:

$$C_p = 2.352 + 4.2882 \times 10^{-2}T - 1.694 \times 10^{-4}T^2$$

where C_p is the molar heat capacity in $\text{cal K}^{-1} \text{mol}^{-1}$ and T is the temperature in kelvin.

The constant volume heat capacity c_v along a locus of Chapman-Jouguet (CJ) states of nitromethane was calculated from varied initial densities ρ_0 , but only provisional values of c_v were obtained [170]. Acquisition of ρ_0 is accomplished by changing the initial temperature, but this also changes the initial internal energy E_0 and creates some problems. An equation for c_v was developed which contained the experimental T_{CJ} , assumed to be constant over the rather narrow range of ρ_0 of the other input data, and $\gamma = c_p/c_v$.

3.2.12.2 Enthalpy of Formation of Nitromethane

A comparison of data for the enthalpy of formation of nitromethane has already been included in Table 9 above.

Experimental Determination of the Enthalpy of Formation of Nitromethane

A new internally consistent experimental data set of $\Delta H_f^{298}(\text{G})$ values for nitromethane and nitrobenzene was compared with the results of one of the most accurate first-principles G4 computation method applied to both atomization and isodesmic reactions. It was shown that the atomization reaction procedure underestimated the values by 6.6 kJ/mol for nitromethane.

The heat of formation of liquid nitromethane calculated from the heat of combustion was derived as $-113 \pm 0.4 \text{ kJ/mol}$ (-26.9 kcal/mol), but this value may not be very accurate [171].

Table 25 gives a summary of enthalpy of formation data for nitromethane. The table shows a surprisingly wide scatter of data. The NASA chemical equilibrium with applications (CEA) [36] and the PROPEP [97] ingredient data lists used -113.1 kJ/mol , and this is assumed to be the most reliable number.

Computation of the Enthalpy of Formation of Nitromethane

The enthalpy and entropy of nitromethane were calculated based on the theorem of corresponding states and presented in the form of temperature-enthalpy and temperature-entropy diagrams [174].

Table 25: Enthalpy of formation of nitromethane.

Molecular mass: 61.040 g/mol					

Molecular mass: 61.040 g/mol

Two experimental values (-80.7 ± 1.2 and -74.5 ± 0.4 kJ/mol = -19.3 ± 0.3 and -17.8 ± 0.1 kcal/mol) for the gas phase heat of formation $(\Delta H)_f^{298}$ of nitromethane vapor have been reported in the literature. Although these values differ by only 1.5 kcal/mol, substantially greater differences in results occur when these differing values were used to calculate other thermodynamic properties. This was especially evident when these two values for the $(\Delta H)_f^{298}$ of nitromethane were used to extrapolate to thermodynamic properties of polynitro compounds. For example, when density functional theory (DFT) was coupled with the use of isodesmic reactions, the $(\Delta H)_f^{298}$ of octanitrocubane turned out to be 672 or 722 kJ/mol (160.6 or 172.6 kcal/mol), depending on which value was used. This discrepancy was examined using several computational models and several levels of theory [175]. The results coupled with a comprehensive review of the literature supported the lower (-80.7 ± 1.2 kJ/mol = -19.3 ± 0.3 kcal/mol) experimental value.

Enthalpies of formation of gaseous nitromethane and nitrobenzene were calculated by Gaussian-4 method with the use of isogyric and isodesmic reactions [176]. Of the two widely used experimental values for nitromethane (-74.5 and -81.0 kJ/mol), the calculations provided strong support for the first one being the more accurate one.

3.2.12.3 Heat of Fusion of Nitromethane

The enthalpy of fusion of nitromethane at 244.77 K is 9.703 kJ/mol and the entropy of fusion at 244.77 K is 39.64 J mol⁻¹ K⁻¹ [94].

3.2.12.4 Heat of Evaporation of Nitromethane

Data for the heat of evaporation of nitromethane at its normal boiling point are summarized in Table 26.

Table 26: Heat of evaporation of nitromethane.

Heat of evaporation		Temperature	Year	Author	References
kJ/mol	kcal/mol	K			
38.37	9.171	298.15	1958	Makovky and Lenji	[93]
38.37	9.171	298.15	1954	McCullough et al.	[95]
38.5	9.22			Meyer, Koehler and Homburg	[96]
38.27	9.15		1986	Coetzee and Chang	[92]

Entropy of evaporation					
J mol ⁻¹ K ⁻¹	cal mol ⁻¹ °C ⁻¹				
128.36	30.68	298.15	1947	Jones and Giauque	[94]

The heat of evaporation in the temperature range 318–374 K can be calculated from [95]:

$$\Delta H_{\text{vap}} = 11730 - 4.9977T - 1.2400 \times 10^{-2}T^2$$

where ΔH_{vap} is the heat of evaporation in cal/mol and T is the temperature in kelvin.

In a different format, the enthalpy of evaporation at saturation pressure as a function of temperature can be calculated from

$$\Delta H_{\text{vap}} = 53.33 \exp(-0.2732T_r)(1 - T_r)^{0.2732}$$

where ΔH_{vap} is the enthalpy of evaporation in kJ/mol, T_r is the reduced temperature $T_r = T/T_c$ and T_c is the critical temperature, 588 K. See also reference [94].

3.2.12.5 Heat of Combustion of Nitromethane

It is known that the combustion is an exothermic process and sometimes heats of combustion are listed as negative numbers to stay in compliance with thermodynamic nomenclature conventions; however, for the sake of simplicity, we are not carrying along the minus signs. Until 1971, the data on the heat of combustion of liquid nitromethane were somewhat contradictory, ranging anywhere from ΔH_{comb} 718 to 709 to 710 kJ/mol (171.7 to 169.4 or 169.8 kcal/mol). These data differed from the results of more recent investigations. Other literature references reported the heat of combustion of nitromethane as 733 ± 0.7 kJ/mol, 730 ± 1.2 kJ/mol or 709 ± 0.6 kJ/mol (175.25 ± 0.18 kcal/mol, 174.4 ± 0.3 kcal/mol or 169.5 ± 0.15 kcal/mol). The heats of combustion of nitromethane and also of dinitromethane were therefore measured more accurately [173]. A sample of nitromethane was purified by drying and fractional distillation and the purity of the sample was estimated at 99.9%.

The heat of combustion of nitromethane was then re-examined and found to be $702.9 \pm 1.2 \text{ kJ/mol}$ ($168.0 \pm 0.3 \text{ kcal/mol}$). The heat of formation of nitromethane in the gas phase is therefore $\Delta H_f^{298} = +80.7 \pm 1.2 \text{ kJ/mol} = +19.3 \pm 0.3 \text{ kcal/mol}$. The enthalpies of combustion of highly pure nitromethane and nitrobenzene have been measured with precise combustion calorimetry and enthalpies of vaporization for both compounds were collected from the literature and evaluated, then compared to results from molecular orbital quantum chemical calculations [178]. Heat of combustion data for nitromethane from different sources are summarized in Table 27.

Table 27: Heat of combustion of nitromethane.

Heat of combustion, ΔU				Data source	References
kJ/mol	kcal/mol	kJ/kg	kcal/kg		
708.8	169.4	11610	2775	Makovky and Lenji 1958; at 293 K	[93]
733.25 ± 0.75	175.25 ± 0.18	12013 ± 12	2871	Holcomb and Dorsey 1949	[16]
709.15 ± 0.59	169.49 ± 2.5	11617 ± 9.7	2776 ± 2.3	Cox and Pilcher 1970	[179]
729.7 ± 1.2	174.4 ± 0.3	11954 ± 21	2857 ± 5	Cass et al. 1958	[172]
703 ± 1	168 ± 0.2	11517 ± 16	2753 ± 3.8	Knobel, Miroshnichenko, and Lebedev 1971	[173]
709.6 ± 0.4	169.6 ± 0.1	11625 ± 6.6	2778 ± 1.6	Lebedeva and Ryadenko 1973	[171]

$$M = 61.040 \text{ g/mol} = 16.38 \text{ mol/kg}$$

Heats of combustion are listed here as positive numbers, although everybody realizes that this is an exothermic process and the numbers should be negative by thermodynamic conventions. When determined calorimetrically under constant volume in a combustion bomb, the energy released is designated as energy, not enthalpy. The enthalpy of combustion is calculated by the equation

$$-\Delta H_c = -\Delta E_c - w - \Delta n(RT)$$

where ΔE_c is the energy of combustion as determined in the calorimeter, w is the Washburn correction, Δn is the change of the number of mols in the reaction, R is the gas constant and T is the absolute temperature. This correction reduces bomb calorimetric data from bomb conditions to conditions in which the reactants and products are in their standard states at atmospheric pressure. ΔH_c and ΔE_c differ only by a few percent. When reading literature data on heat of combustion, it is not always clear if this correction has been applied or not.

Table 9 in chapter “Nitroaliphatic Compounds” of *Encyclopedia of Oxidizers* contains heat of combustion data on ten nitroalkanes based on data from Holcomb and Dorsey [16]. See also [94, 180].

3.2.13 Solubility of Nitromethane

3.2.13.1 Solubility of Nitromethane in Water

Nitromethane is only sparingly soluble in water. For most applications, one will want to use nitromethane as dry and water-free as possible; however, there are a few applications where the dissolved water will help, for instance in lowering the flame temperature of nitromethane in a gas (steam) generator. Based on IR measurements, nitromethane may form a hydrate adduct with water. Nitromethane forms an azeotrope with water. At 293 K, 2.2 mL of water will dissolve in 100 mL of nitromethane. The solubility of nitromethane in water increases with temperature (Table 28).

Table 28: Solubility of nitromethane in water.

Temperature		Solubility, mass-% nitromethane in water
K	°C	
268	−5	8.065
291	18	10.53
310	37	12.55
321.65	48.5	14.48
330	57	16.08
341.65	68.5	18.97
348.65	75.5	21.54
349.65	76.5	22.33
358.65	85.5	25.92
367	94	32.02
372.65	99.5	39.19
375	102	45.2
376.75	103.6 (critical temperature of saturation)	59.6

Data source: [181]

Henry's Law constants for solubility of nitromethane in water at 298.15 K given in the literature vary anywhere between 35 and 45 mol kg^{−1} bar^{−1} [91]. At 293 K = 20 °C, 9.5 mL of nitromethane will dissolve in 100 mL of water.

3.2.13.2 Solubility of Water in Nitromethane

At 293 K = 20 °C, 2.2 mL of water will dissolve in 100 mL of nitromethane. In other units of measurement, the water content in saturated nitromethane is 1.8 mass-% at 293 K, 2.1 mass-% at 298 K, and 7.6% at 343 K.

3.2.14 Molecular Structure of Nitromethane

When looking at the molecular structure of nitromethane (Figure 6), one must remember that it is an isomer of methyl nitrite, which is much less stable than nitromethane. Electron diffraction studies lead to the following structure for nitromethane [182].

Figure 6: Molecular structure of nitromethane.

The molecular structure of nitromethane is characterized by the partially impeded rotation of the NO_2 and CH_3 groups around the axis of the C—N bond. Sometimes studies of the molecular structure and spectra of nitromethane are combined with an examination of nitrobenzene, both molecules sharing a C—N bond, but with different degrees of impedance of the free rotation. For the three highest occupied orbitals and the lowest unoccupied one, electron density is concentrated at the NO_2 end of the molecule.

The crystal structure of solid nitromethane is orthorhombic, space group $P 2_1 2_1 2_1$ with cell parameters of $a = 5.1832 \text{ \AA}$, $b = 6.2357 \text{ \AA}$, $c = 8.5181 \text{ \AA}$ at $T = 4.2 \text{ K}$, and $Z = 4$. Two models were used to describe the thermal motion of the methyl group, one with anisotropic temperature factors for the hydrogen atoms constrained to correspond to a threefold rotation around the C—N bond, and the other treating the group as a rigid body, with a torsional oscillation about the C—N bond axis [183].

Many investigations of nitromethane in any of the three physical states have concentrated on the internal rotation of the two molecule halves around the C—N bond and the steric hindrance to free rotation. Intramolecular hydrogen bonding forces are exerted between the oxygen on the nitro group and the hydrogen on the methyl group. The thawing of the rotation adds another degree of freedom to the possible modes of fundamental vibrations. The internal rotation has been studied by IR, microwave, and neutron scattering spectrometry.

The torsional transitions and tunneling splitting of solid nitromethane NO_2CH_3 and NO_2CD_3 were measured by inelastic neutron scattering and analyzed as functions of pressure and temperature [184]. Contrary to all previously observed pressure dependence of hindered rotors, the ground state splitting increased with pressure while the torsional frequencies decreased [185]. The barrier of rotation in solid nitromethane is very small: 25 kJ/mol (6 kcal/mol). Quasi-elastic scattering spectra have been obtained for several values of momentum transfer at 5 temperatures between 50 and 150 K. The

spectra were shown to be consistent with jumps of 120° about an axis coincident with the C—N bond. The temperature dependence of the residence time indicated a barrier of only 979 J/mol (234 cal/mol). An inelastic neutron spectrum obtained at 4.2 K suggested a tunnel splitting of the torsional ground state of 0.045 ± 0.005 meV, which was consistent with the derived activation energy [186, 187].

In the example of polynitroalkanes it was shown by computation that fluorine substitution for the hydrogen atoms practically did not affect the value of the dissociation energy of C—N bond, but chlorine (and also bromine or iodine) atoms caused a considerable decrease in the activation energy of the radical gas phase decomposition and C—N bond length, which was even larger than that in the case of introduction of an additional nitro group into the molecule. Consecutive substitution of hydrogen atoms by fluorine atoms in nitromethane leads to monotonous increase in C—N interatomic distance and decrease in $r(\text{NO})$ value [188].

In addition to experimental measurements of various spectra that reveal the molecular structure of nitromethane, numerous computational studies have attempted to interpret the observed spectra and predict physical properties of nitromethane in the vapor, liquid, and solid state from *a priori* assumptions. These calculations were performed not so much for the interest in nitromethane alone, but mostly to develop methods that can be applied to other, more complex and more important nitro compounds. The structure of nitromethane was the easiest to model and would be the starting point to prove the validity of the model by comparing computational to experimental results. In many commercial and military explosives, the stability of the molecule is determined by the lability of the C—NO₂ bond. A better understanding to the effect of adjacent atoms and atom groups on the stability or lability of the C—NO₂ bond will allow chemists to synthesize thermally more stable explosives and rocket propellants.

3.2.14.1 Computational Studies of the Molecular Structure of Liquid Nitromethane

Ab initio and modified neglect of diatomic overlap (MNDO) calculations were performed to study the molecular structure and vibrational frequencies of nitromethane and the nitromethyl radical [189]. For nitromethane, the two rotational conformers were predicted to differ in energy by only 0.01 kcal/mol. Vibrational frequencies of the staggered and eclipsed conformations were compared to experimental frequencies. Similar studies were done for the nitromethyl radical, an intermediate in the nitromethane decomposition.

Molecular dynamic simulations of liquid nitromethane has been carried out in which a density functional procedure was used to compute the properties needed to establish the intermolecular force field [190, 191], also for liquid nitromethane shocked to very high pressures [192]. The intermolecular force field was subsequently updated by further density functional calculations. Because of the high dipole moment and presence of the aci-form, molecules are associated and clustered. The first and second shells of neighbors were found to be at radii of about 6 and 11 Å from a given ni-

tromethane molecule. The O—H partial pair correlation functions indicated the presence of C—H...O hydrogen bonding.

A potential energy function with harmonic intramolecular and Lennard-Jones plus Coulombic intermolecular terms was tested in molecular dynamics simulations of liquid nitromethane [193]. Parameters were adjusted iteratively until satisfactory agreement with density functional pair calculations and experimental data was achieved. The properties computed were the heat of vaporization, dielectric constant, self-diffusion coefficient, density, heat capacity at constant pressure, single molecule and collective dipole moment reorientation times, the vibrational spectrum and the effect of increasing pressure upon the C—N stretching frequency. The results were in reasonable accord with experimental results, the greatest discrepancy being for the dielectric constant.

Nitromethane dimers may form in the vapor phase and in the liquid phase due to “tail-to-end” orientation of two neighboring molecules. Three optimized geometries of nitromethane dimer have been calculated [194]. Dimer binding energies have been corrected for the basis set superposition error and the zero point energy. Computed results indicated that the cyclic structure of $(\text{CH}_3\text{NO}_2)_2$ is the most stable of three optimized geometries, whose corrected binding energy is 17.29 kJ/mol. In the optimized structures of nitromethane dimer, the intermolecular hydrogen bond has not been found. The charge-transfer interaction between CH_3NO_2 subsystems is weak. The correlation interaction energy makes a small contribution to the intermolecular interaction energy of the dimer.

A quantum-chemical study of reactions leading to the formation of *aci*-nitromethane (*aci*-NM) and *aci*-dinitromethane (*aci*-DNM) and their decomposition with elimination of water employed an *ab initio* restricted Hartree-Fock (RHF) method with inclusion of electron correlation, a DFT approach and a semiempirical method [195]. The formation of *aci*-NM and *aci*-DNM was found to be the limiting step of the mechanisms under study. For dinitromethane the barrier to reaction was substantially lower than for nitromethane. The estimates of the heights of the barriers to formation found from DFT calculations (258 kJ/mol for *aci*-NM and 218.5 kJ/mol for *aci*-DNM) were suggested to be the most reliable.

A classical potential consisting of both intramolecular and intermolecular terms that was initially developed for the simulation of crystalline nitromethane has been used to investigate the dynamics of liquid nitromethane at various temperatures and pressures [196]. The validation of the proposed potential model was done for a large number of static and dynamic properties including the heat of vaporization, the variation of density with temperature and pressure, the thermal expansion coefficient, the self-diffusion coefficients, the viscosity coefficient, the dielectric constant, the bulk modulus and the variation of vibrational frequencies with pressure. The analyses performed using constant pressure and temperature and constant volume and temperature molecular dynamics simulations showed that the potential vs. distance method accurately reproduced the structural properties of liquid nitromethane at ambient

pressure in the temperature range 260–374 K as well as the compression effects up to 14.2 GPa.

Simulation and diffraction (X-ray diffraction, XRD and neutron diffraction) studies were compared in an effort to determine the liquid structure of nitromethane [197]. The diffraction methods were performing very well in the determination of intramolecular structure, but they did not give detailed structural information on the intermolecular structure. The good agreement between the diffraction experiments and the results of molecular dynamics simulations encouraged the use of simulations using partial radial distribution functions and orientational correlation functions for a more detailed description of the liquid structure. Liquid nitromethane can be described as a molecular liquid without strong intermolecular interactions such as hydrogen bonding but with detectable orientational correlations resulting in preferential anti-parallel ordering of neighboring molecules.

An integral equation theory for molecular liquids, Reference Interaction Site Model (RISM), was applied to understand the liquid structure of nitromethane [198]. In the theory, liquid structure can be described by a set of paired correlation functions. With the aid of *ab initio* molecular orbital calculations, it was possible to correlate representative peaks with specific configurations of nitromethane molecules.

3.2.14.2 Computational Studies of the Structure of Solid Nitromethane

At room temperature nitromethane is a liquid and much modeling has been done for the liquid, but the interest in the molecular structure of solid nitro compounds as energetic materials is actually higher than that in liquid nitro compounds. Therefore, additional modeling was done on solid nitromethane instead of liquid nitromethane.

Monte Carlo calculations of the crystal lattice parameters of solid nitromethane were performed to obtain sufficient information concerning the intermolecular interactions between molecules of nitromethane in order to produce, via computer simulation, a reliable EOS and other related properties in the condensed phase [199]. The results compared well to experimental investigations of properties of the crystal by neutron spectroscopy at 4.2 K and pressures below 1 GPa ([185, 187, 200]).

The sensitivity of nitromethane crystals to shock initiation shows anisotropy, where the sensitivity is orientation-dependent [201].

The dynamics of a nitromethane crystal as a function of temperature and pressure can be described by a classical potential method [202, 203]. The intramolecular part of the potential would be taken as superposition of bond stretching, bond bending and torsional angle twitching terms. These terms were parameterized on the basis of the geometric and spectroscopic data obtained using *ab initio* molecular orbital calculations performed on an isolated molecule. The analyses performed using constant pressure and temperature molecular dynamic simulations and molecular packing calculations indicated that the proposed potential model is able to accurately reproduce the changes of the structural crystallographic parameters as functions of tem-

perature or pressure. In addition, the calculated bulk modulus of nitromethane was found to be in excellent agreement with the corresponding experimental results. The predicted and experimentally observed 45° change in methyl group orientation in the high-pressure regime relative to the low-temperature configuration agreed with each other. The analysis of the linear expansion coefficients and linear compression data indicated anisotropic behavior for the unit cell edges.

The combined effect of pressure and molecular vacancies on the atomic structure and electronic properties of solid nitromethane, a prototypical energetic material, was theoretically studied using a self-consistent charge density-functional tight-binding method [204]. Changes induced in the band gap of this system by uniform and uniaxial strain of up to 70%, corresponding to static pressure in the range of up to 200 GPa, and the effects of molecular vacancies with densities ranging from 3 to 25% have been considered. A surprising finding was that uniaxial compression of about 25–40 GPa along the *b* lattice vector causes the C–H bond to be highly stretched and leads to proton dissociation. This event also occurs under isotropic compression but only at much higher pressure, being indicative of a detonation chemistry which is preferential to the pressure anisotropy.

The structural, vibrational, and electronic properties of solid nitromethane under hydrostatic pressure of up to 20 GPa have been studied using a density functional theory method [205]. The changes of cell volume, lattice constants, and the molecular geometry of solid nitromethane under hydrostatic loading, and the bulk modulus B_0 were computed, and its pressure derivative B_0' was fitted from the volume-pressure relation. The theoretical results were then compared with available experimental data. The electron band gap of nitromethane changed under high pressure. Based on the optimized crystal structures, the vibrational frequencies for the internal and lattice modes of the nitromethane crystal at ambient and high pressures were computed, and the pressure-induced frequency shifts of these modes were identified.

Structural change of crystalline nitromethane and the formation of hydrogen bonds under high pressure were simulated by molecular dynamic calculations [206]. Under high pressure, the angles between C–N bonds and X, Y, and Z axes have changed. Calculations of pair correlation function $g(r)$ of O and H atoms indicated a new peak near 1.6 Å, which indicates the formation of the hydrogen bonds between O and H atoms. The distribution of the angles of the C–N bonds orientations, the distribution of the dihedral angle of CNOO, and the charge distribution of nitromethane molecules were calculated under various pressure conditions and a comparison was made between low and high pressure structures. Hydrogen bonding has an effect on stability of explosive materials.

The structural and vibrational properties of solid nitromethane were studied using first principles density functional calculations [207]. The ground state properties were calculated using a plane wave pseudopotential code with either the local density approximation, the generalized gradient approximation, or with a correction to

include van der Waals interactions. The calculated equilibrium lattice parameters and volume using a dispersion correction were found to be in reasonable agreement with experimental results. The optical properties of this material, namely the absorptive and dispersive part of the dielectric function, and the refractive index and absorption spectra were calculated and the contribution of different transition peaks of the absorption spectra were analyzed. The static dielectric constant and refractive indices along the three nonequivalent crystallographic axis directions indicated that this material has a considerable optical anisotropy.

3.2.14.3 Changes of the Molecular Structure of Nitromethane under Very High Static Pressure

It is well known that rapid compression of nitromethane in a shock wave will cause it to explode. The question is if there are structural changes in the molecule preceding the detonation that make it more sensitive to decomposition. It was attempted to detect structural changes by slowly subjecting nitromethane to very high static pressure that might lead to ignition.

The structure of single crystals of nitromethane in diamond anvil cells has been studied by XRD at room temperature and pressures of 0.3–6 GPa [208]. The crystal structure was similar to the low temperature, ambient pressure structure. At 3.5 GPa, the methyl group was rotated 45° from the position in the low pressure, low temperature form. Raman spectra taken at pressures up to 11.7 GPa showed that all molecular vibrational frequencies increased with pressure.

In addition to reactions with proton acceptors, the *aci* form of nitromethane may also form under the influence of high pressure. Static high pressure (~2 GPa) produced an increased concentration of the *aci* ion of nitromethane [209]. The presence of the *aci* form was inferred from accelerated hydrogen/deuterium isotope exchange between CH₃NO₂ and CD₃NO₂ induced by pressure. The isotope exchange was followed by Raman spectra measurements and by ¹³C NMR. This observation provided an explanation for the pressure-dependent self-explosive behavior of nitromethane.

The room temperature pressure-induced reaction of nitromethane has been studied by means of infrared spectroscopy in conjunction with *ab initio* molecular dynamic simulations [210]. The evolution of the IR spectrum during the reaction has been monitored at 32.2 and 35.5 GPa performing the measurements in a diamond anvil cell. The simulations allowed the characterization of the onset of the high-pressure reaction, showing that its mechanism had a complex bimolecular character and involved the formation of the *aci* ion of nitromethane. On decompression of the sample, after the reaction, a continuous evolution of the product was observed with a decomposition into smaller molecules. The major reaction product on decompression is *N*-methylformamide, the smallest molecule containing the peptide bond. The high-pressure reaction of crystalline nitromethane under illumination

at 458 nm was also experimentally studied. The reaction threshold pressure was significantly lowered by the electronic excitation through two-photon absorption, and methanol and ammonium carbonate were also formed.

3.2.14.4 Crystal Structure of Solid Nitromethane

The crystal structure of solid nitromethane is orthorhombic, space group $P2_12_12_1$ with cell parameters of $a = 5.1832 \text{ \AA}$, $b = 6.2357 \text{ \AA}$, $c = 8.5181 \text{ \AA}$ at $T = 4.2 \text{ K}$, and $Z = 4$ [183].

It is possible that a detonation front moving through solid nitromethane will liquefy the solid before it detonates. Modeling the melting process gives a better understanding of detonation propagation in solid nitromethane.

Molecular dynamic studies of melting of nitromethane have been carried out using two methods: (1) void-nucleated melting with the gradual heating of the lattice and (2) equilibration of coexisting liquid and solid phases [211]. The results were in near agreement with each other. The values of the melting temperature T_m computed by using the intermolecular interaction potential method were found to be in good agreement with the experimental data at various values of pressure ranging from 1 atm to 30 kbar. A comparison of computed T_m with and without the presence of molecular vibrations revealed that T_m is insensitive to the intramolecular interaction term of the potential energy function, but depends strongly on the intermolecular interactions, particularly the Coulombic term.

It is unlikely that nanoparticles of frozen nitromethane would be used as rocket propellants, but the association of several (many) molecules first into adducts, then into clusters, then into nanoparticles and then into solid massive nitromethane crystals has been modeled mathematically [212]. This is the reverse process of melting. The melting temperatures predicted by the various properties were consistent with one another and showed that the melting temperature increased with particle size, approaching the bulk limit for the largest particle.

Studying the thermodynamic melting point of crystalline nitromethane by molecular dynamic simulation computations, the melting mechanism of superheated crystalline nitromethane, and the physical properties of crystalline and glassy nitromethane showed that the maximum superheating and glass transition temperatures of nitromethane were 316 and 160 K, respectively, for heating and cooling rates of $8.9 \times 10^9 \text{ K/s}$ [102]. Using the hysteresis method and by taking the glass transition temperature as the supercooling temperature, a value of 251 K for the thermodynamic melting point was in excellent agreement with the two-phase result of 255.5 K and measured value of 244.73 K. In the melting process, the nitromethane molecules begin to rotate about their lattice positions in the crystal, followed by translational freedom of the molecules. A nucleation mechanism for the melting was illustrated by the distribution of the local translational order parameter. The thermal expansion coefficient and bulk modulus were predicted to be about two or three times larger in crystalline nitromethane than in glassy nitromethane. The vibrational density of states was almost identical in both phases.

The melting of nitromethane initiated at solid-vacuum interfaces has been investigated using molecular dynamic simulations with a realistic force field [213]. The calculated melting point (251 ± 5 K) was in good agreement with experimental results (244.73 K) and values obtained previously (approximately 255.5 and 266.5 ± 8 K) using other simulation methods. There was a slight dependence of the melting temperature on the orientation of the exposed crystallographic face.

Angle dispersion X-ray diffraction experiments on nitromethane single crystals and powder were performed at room temperature as a function of pressure up to 19.0 and 27.3 GPa, respectively, in a membrane diamond anvil cell [214]. The atomic positions were refined at 1.1, 3.2, 7.6, 11.0, and 15.0 GPa using the single crystal data, while the EOS was extended up to 27.3 GPa, which is close to the nitromethane decomposition threshold pressure at room temperature in static conditions. The crystal structure was found to be orthorhombic, space group $P2_12_12_1$, with four molecules per unit cell, up to the highest pressure. In contrast, the molecular geometry underwent an important change consisting of a gradual blocking of the methyl group libration about the C–N bond axis, starting just above the melting pressure and completed only between 7.6 and 11.0 GPa. Above this pressure, the orientation of the methyl group is quasi-eclipsed with respect to the N–O bonds. This conformation allows the build-up of networks of strong intermolecular $O \cdots H-C$ interactions mainly in the *bc* and *ac* planes, stabilizing the crystal structure.

Molecules subjected to shock waves will, in general, undergo significant intramolecular distortion and exhibit large amplitude orientational and translational displacements relative to the unshocked material. A molecular dynamics study of the response of crystalline nitromethane subjected to supported shock waves propagating normal to (100) crystal face was performed using the non-reactive but vibrationally accurate force field method [215]. Shocks were initiated with assumed impact velocities of $U_p = 0.5, 1.0, 2.0$, and 3.0 km/s in crystals at initial temperatures of $T_0 = 50$ and 200 K. Structural and dynamic properties of the material corresponding to orientation in the lattice, translational symmetry, and mass transport were computed as functions of time. The results provided clear evidence of melting for shocks initiated by impacts of at least $U_p = 2.0$ km/s and provided insights into the evolution of changes at the molecular mode level associated with the onset of the melting instability in shocked crystal.

The reverse of melting, the crystallization of nitromethane from the melt on the (100), (010), (001), and (110) crystal surfaces at 170–220 K has been investigated using constant volume and temperature molecular dynamic simulations with a realistic, fully flexible force-field method [216]. The crystallization process and the nature of the solid-liquid interface have been investigated by computing the molecular orientations, density, and radial distribution functions as functions of time and location in the simulation cell. During crystallization the translational motion of the molecules ceases first, after which molecular rotation ceases as the molecules assume proper orientations in the crystal lattice. The methyl groups are hindered rotors in the liquid;

hindrance to rotation is reduced on crystallization. The width of the solid-liquid interface varies between 6 and 13 Å (about 2–5 molecular layers) depending on which crystal surface is exposed to the melt and which order parameter is used to define the interface.

3.3 Chemical Properties of Nitromethane

Nitromethane can be stored at room temperature without decomposition. Its storage stability is very good. It has been observed that nitromethane containers may create negative pressure, possibly by absorption of oxygen from the air in the ullage, but this does not affect the purity of the product.

The oxygen balance of nitromethane is –39.3%. It is quite fuel-rich and any attempt to use it as a monopropellant without additional oxidizer will result in a very sooty exhaust. Attempts to clean up the exhaust by adding oxidizers to the nitromethane may result in detonable mixtures, which would be undesirable for rocket propellants.

3.3.1 Acid-Base Reactions of Nitromethane

Nitromethane is a very weak proton acceptor, as shown by a pK_a value near –12 for its conjugate acid in aqueous sulfuric acid or acetonitrile, $pK_a = -9.5$. By comparison, nitromethane is by no means a very weak proton donor, as shown by its pK_a value of 10.2 in aqueous solution. The cause of this considerable acidity is evident from a consideration of the resonance forms of nitromethane (1) and of its conjugate base (2):

The major resonance stabilization of the anion derives from the tautomeric structure (c). It is also necessary to explicitly consider the effect of tautomerism in the determination of the pK_a values of nitroalkanes.

transition state was calculated to lie 237 kJ/mol (56.7 kcal/mol) above nitromethane (with zero-point energy). The C—N bond dissociation energy was 216 kJ/mol (51.7 kcal/mol).

Tautomerism is competitive with many other processes that occur during detonation [218].

The mechanism of the unimolecular rearrangement between nitromethane and methyl nitrite isomers and the CH_3NO_2 potential energy surface was constructed using different molecular orbital and density functional theory methods including a few lower lying isomeric intermediates [219]. The C—N bond dissociation energy was 251 ± 8 kJ/mol (60 ± 2 kcal/mol) in line with available experimental results. The computations demonstrated that the methyl migration involves a “tight” transition state whose electronic wave function is dominated by the Hartree-Fock configuration. Calculations are thus internally consistent indicating that the energy of the transition state for 1,2- CH_3 shift is at least 25 kJ/mol (6 kcal/mol) above the $\text{CH}_3 + \text{NO}_2$ asymptote, which does not agree with experimental findings.

The low-lying energy pathways for the decomposition/isomerization of nitromethane have been investigated using different molecular orbital methods [220]. The results showed that in addition to the commonly known $\bullet\text{CH}_3 + \bullet\text{NO}_2$ products formed by direct C—N bond breaking and the *trans*- CH_3ONO formed by nitro-nitrite isomerization, nitromethane can also isomerize to *cis*- CH_3ONO via a very loose transition state lying 248 kJ/mol (59.2 kcal/mol) above CH_3NO_2 . Kinetic results indicated that in the energy range of 247 kJ/mol (59 kcal/mol), production of $\text{CH}_3\text{O}\bullet + \bullet\text{NO}$ will be dominant, whereas above the C—N bond-breaking threshold, the formation of $\bullet\text{CH}_3 + \bullet\text{NO}_2$ sharply increases and becomes dominant.

3.3.3 Hypergolic Ignition of Nitromethane

When using nitromethane as a rocket propellant, it would be useful to have a hypergolic reagent that can be injected along with nitromethane for a few seconds to get the reaction started. Sodium-potassium alloy produced an immediate hypergolic reaction with nitromethane and has been used successfully many times in initiating the decomposition of nitromethane in a 220-N (50-lb_f) thrust chamber [221]. Concentrated solutions of lithium, sodium, or potassium in ammonia produced a hypergolic reaction with nitromethane within a few seconds of contact. Chlorine trifluoride can react explosively with nitromethane under certain conditions and was not recommended.

3.3.4 Decomposition Reactions of Nitromethane

Because nitromethane has often been used as a simple model substance for other, more complex nitro compounds, most of them used as explosives rather than rocket propellants, there has been much work done on the thermal decomposition of nitromethane. The controlled thermal decomposition of nitromethane would also be

of interest for gas generators using nitromethane in a thermal bed and those using catalytic beds to facilitate the start-up of the reaction. The catalytic decomposition of nitromethane and practical applications of nitromethane in rocket engines and gas generators will be discussed in *Encyclopedia of Monopropellants*. Here we summarize only academic studies of reaction kinetics that can be safely conducted indoors on a bench top.

3.3.4.1 Slow Thermal Decomposition of Nitromethane

Both the slow and the fast thermal decomposition of nitromethane have been studied in exhaustive detail because nitromethane is a simple molecule, serves as a standard model for more complex nitro compounds used as commercial and military explosives, and can potentially be used as a monopropellant in rockets. Although it is a simple molecule, the decomposition reactions are nevertheless complex and can follow several pathways. In this section we deal only with homogeneous (liquid phase and vapor phase) decomposition of nitromethane. The heterogeneous, catalytic decomposition of nitromethane will be discussed in a later section on the use of nitromethane as a rocket propellant.

Kinetic rates of nitromethane vapor decomposition in a constant volume apparatus were derived from pressure changes at constant temperature for temperatures ranging from 663 to 693 K = 390–420 °C [222]. The times necessary for 25, 50, and 75% of the total pressure increase were measured as intermediate data points.

Above 573 K (300 °C), nitromethane decomposed slowly. Between 573 and 633 K, nitromethane occasionally detonated. Runaway decomposition of 2-mL samples of nitromethane in a stainless steel bomblet started at 684 K (411 °C) [123]. There was only slow decomposition below 673 K (400 °C) indicated by a pressure rise in the bomblet.

The decomposition of nitromethane was studied in a static system. Two procedures for determining the rate of decomposition were considered: the manometric method, and the infrared, *in situ* method. The activation energy of slow thermal decomposition in a first-order reaction was 221.7 kJ/mol (53 kcal/mol) [221]. The reaction rate equation was

$$k_1 = 7.8 \times 10^{15} \exp(-53300/RT)$$

where k_1 was the rate constant in min^{-1} and T was the temperature in kelvin.

Thermal decomposition of nitromethane at different heating rates was measured by DSC [223]. The data from different heating rates were analyzed with the isoconversional Friedman method. The heat of decomposition, exothermic onset temperature, time to reach the maximum rate under the adiabatic condition (TMR_{ad}) and the self-accelerating decomposition temperature (SADT) were derived via the advanced thermokinetic software and an advanced thermokinetic and thermal safety software package. The onset exothermic temperature of nitromethane tended to increase with the decomposition heat decrease while the scanning rate was rising. The time at the initial temperature to reach the maximum rate under adiabatic conditions was 24 h at

422 K (149 °C). The temperature to reach the maximum rate under adiabatic conditions in a package of nitromethane with an inner radius of 50 cm was 434 K (161 °C).

3.3.4.2 Kinetics of Nitromethane Decomposition

When designing a rocket using nitromethane as the propellant one must know the decomposition kinetics. Decomposition will take place by homogeneous gas (vapor) phase reactions and also as heterogeneous reaction on the walls or on the surface of catalysts. Kinetic studies of homogeneous nitromethane vapor decomposition are usually conducted at low pressures or at low partial pressures with dilution by inert gases to avoid detonations. The thermal homogeneous decomposition of nitromethane was studied by a static method over the temperature range 653–703 K (380–430 °C) at pressures between 26 and 53 kPa (200 and 400 mm Hg) and shown to be a first order reaction with a rate constant of

$$k = 10^{14.6} \exp(-53600/RT) \text{ s}^{-1}$$

The dissociation energy of the C–N bond in nitromethane was estimated to be 222 kJ/mol (53 kcal/mol). The main products were NO, CH₄, CO, and H₂O, with some CO₂ and small quantities of C₂H₆, C₂H₄, and N₂O [224, 225]. The initial step was assumed to be

Kinetic tests indicated that the first step of decomposition is the fission of the C–N bond [226].

A study of the thermal decomposition of nitromethane was made by a flow method, with nitrogen as carrier gas, and the progress of the reaction was followed by polarographic analysis of the effluent from the reactor [227]. The decomposition followed a first-order law, and over the range 693–753 K (420–480 °C) the rate could be represented by the equation

$$k = 2.7 \times 10^{13} \exp(-50000/RT) \text{ s}^{-1}.$$

At 693 K (420 °C), *k* was in good agreement with the value obtained by the static method, but at higher temperatures the observed rate was lower than that reported previously. Although the energy of activation is close to that required to break the C–N bond, the high initial yield of formaldehyde obtained in the flow-method experiments suggested that the rate is in part determined by an intramolecular rearrangement.

The thermal decomposition of nitromethane at 628 K (355 °C) was studied in the pressure range from 1.24 to 2.07 MPa (180–300 psia) [228]. The presence of large amounts of hydrogen cyanide in the exhaust suggested a mechanism other than the simple

reaction which occurs at lower pressures. Addition of NO inhibited the rate of CH_3NO_2 decomposition.

In the range 700–1200 K the reaction rate of the reaction $\text{CH}_3\text{NO}_2 \rightarrow \bullet\text{CH}_3 + \text{NO}_2$ is

$$k = 2.50 \times 10^{11} \exp(E_a/RT) = 2.50 \times 10^{11} \exp(1.79 \times 10^5/RT)$$

where E_a is the activation energy in J/mol and T is the temperature in kelvin [229]. See also reference [230].

A Variable Encounter Method was used to study the pyrolysis of nitromethane vapor at temperatures from 816 to 1092 K with two reactors of differing geometry having fused silica surfaces [231]. The probability of reaction per collision with the reactor surface was measured. Nitromethane is one of the more efficient energy transfer agents; however, in addition to the size (vibrational eigenstate density) and the polarity of the molecules, the nature of the hot surface also seemed to play a role.

The homogeneous gas-phase decomposition of nitromethane was modeled and subjected to a sensitivity analysis of the main operating parameters (temperature, pressure) [232].

The decomposition of nitromethane was investigated in a shock tube at 990–1600 K, initial concentration of nitromethane in a mix with Ar in the range of 30–10000 ppm, and maximum variation of pressure behind the shock waves by a factor of 240 [233]. The consumption of nitromethane was observed at $\lambda = 230$ nm and the yield of NO_2 radicals was measured at $\lambda = 405$ nm. The elementary rate constants (k_1) of nitromethane decomposition were measured for:

Even in diluted mixes with Ar the process of nitromethane decomposition could be described by exponential dependence only at its initial stages and at high temperatures. The rate constants for low ($k_{1,0}$) and high ($k_{1,\infty}$) pressure limits were:

$$k_{1,0} \approx 10^{17.3} \exp(-42/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1},$$

and

$$k_{1,\infty} \approx 10^{16.2} \exp(-59.7/RT) \text{ s}^{-1}.$$

Data for the thermal decomposition of nitromethane vapor over the temperature range from 580 to 700 K at pressures of 0.5 kPa to 4.04 MPa (4 Torr to 40 atm) were critically analyzed [234]. On the basis of published literature data, the rate constants k of nitromethane decomposition at the upper pressure limit were determined and were in good agreement with the results of extrapolation of the high temperature (1000–1400 K) k values [233] to lower temperatures. The reasons why the nitromethane decomposition rate constants differed by two orders of magnitude at low temperatures are up for discussion. A general expression for the nitromethane

decomposition rate constant at the upper pressure limit over the 580–1400 K temperature range was determined as:

$$k = (1.8 \pm 0.7) \times 10^{16} \exp[(-58.5 \pm 2)/RT] \text{ s}^{-1}$$

These data disproved the hypothesis that a nitro-nitrite rearrangement takes place during the nitromethane decomposition at low temperatures.

3.3.4.3 Effects of Additives on Kinetic Rates of Nitromethane Decomposition

It had been postulated that the formation of nitrogen dioxide is the first step in the thermal decomposition of nitromethane. If this is true, the following reaction maybe important:

In this instance the addition of nitrogen dioxide to nitromethane should result in an increased rate of decomposition. From the results with added nitrogen dioxide it must be concluded that if nitrogen dioxide is formed in the thermal decomposition of nitromethane this reaction cannot be important. Both nitrogen dioxide and nitric oxide, if present in equal amounts, appeared to inhibit the decomposition of nitromethane at 628 K (355 °C) and 1.3–1.5 MPa (190–220 psia) to the same extent [235, 236].

It is possible that the inhibitory action of nitrogen dioxide is actually attributable to nitric oxide. Nitric oxide is known as a free radical scavenger and usually has a noticeable effect on the kinetic rate of reactions that involve free radicals. Adding catalytic agents to nitromethane that are also effective in decomposing NO will enhance the rate at which nitromethane decomposes in a rocket engine [237].

It had been observed that the addition of oxygen to nitromethane in a rocket motor considerably lowered the characteristic length (L^*) and the pressure required for stable operation. Because L^* is related to the time the propellant remains in the combustion chamber, it was assumed that the function of oxygen was to increase the rate of decomposition of nitromethane sufficiently to effect complete decomposition in a shorter time than is otherwise possible. If this explanation is valid, one would expect that under the conditions of the present investigation the addition of 13% oxygen should result in a considerable increase in the percentage of nitromethane decomposed, but experiments showed that the addition of oxygen did not affect the rate of decomposition of nitromethane for 5, 15, and 30 min of reaction time.

A study was made of the decomposition of nitromethane in the presence of various inhibitors (NO, toluene, *cis*-2-butene), and at various ratios of the surface area and volume of the reaction vessel [238]. The decomposition of nitromethane proceeded as a homogeneous monomolecular reaction.

The thermal explosion times of liquid nitromethane were measured at 1, 10, and 50 kbar and between 433 and 653 K (160 and 380 °C) [239]. At constant pressure, the explosion time decreased as the temperature increased. At constant temperature, the explosion time decreased as the pressure increased. For a constant explosion time of

10 s, at 1 kbar the required temperature was 642 K = 369 °C, at 10 kbar it was 600 K = 327 °C and at 50 kbar it was 498 K = 225 °C (Table 29). The increase in decomposition rate with increasing temperature is explainable by Arrhenius type kinetics. At 498 K = 225 °C, an increase by a factor of 5 in pressure caused a decrease by a factor of 50 in explosion time. Similar tests were performed with three dinitropropane isomers in an effort to determine the effect of hydrogen in the α -position on the rates of decomposition and the ease of the C—N bond rupture.

Table 29: Arrhenius constants and time to explosion for liquid nitromethane at high pressures.

Pressure	Pre-exponential factor	Activation energy		Temperature for time to explosion of 10 s	
kbar	s ⁻¹	kJ/mol	kcal/mol	K	°C
1	10 ⁶	83.7	20	642	369
10	10 ^{5.3}	92	22	600	327
50	10 ⁴⁰	531	127	498	225

Data source: [239]

It is well known that the detonability and thermal decomposition of nitromethane are greatly enhanced by the addition of organic amines, forming some of the very sensitive *aci*-salts. The thermal decomposition of nitromethane by itself was compared to the accelerated decomposition of nitromethane activated by addition of diethylamine. Laser-initiated decomposition of single aerosol particles in the source region of a time-of-flight spectrometer, followed by vacuum ultraviolet laser ionization and mass analysis of the reaction products, revealed the identity of species formed in the early stages of condensed-phase decomposition in nitromethane and nitromethane-diethylamine mixtures [240]. In pure nitromethane, the initial stages of decomposition can be characterized by unimolecular processes. At near-threshold energies, the cleavage of the C—N bond to form $\bullet\text{CH}_3$ and $\bullet\text{NO}_2$ dominated the dynamics, and at higher energies evidence of rearrangement to methyl nitrite was found, followed by the formation of $\text{CH}_3\text{O}\bullet$ and $\bullet\text{NO}$. In nitromethane seeded with 0.1% diethylamine, an additional channel was observed which produced ionic intermediates. Detection of protonated diethylamine and the nitromethane *aci*-anion confirmed that an acid-base reaction is involved in this case. Deuterium labeling studies indicated a hydrogen atom transfer reaction between the nitromethane *aci*-anion and neutral nitromethane that produced the weakly bound nitromethane anion, the precursor to $\bullet\text{CH}_3$ and $\text{}^-\text{NO}_2$.

3.3.4.4 Effects of Pressure on Nitromethane Decomposition

The thermal decomposition of liquid nitromethane was studied at 608 K (335 °C) and in the pressure range from 1.24 to 2.07 MPa (180–300 psia) [228]. Large quantities of nitric

oxide inhibited the rate of disappearance of nitromethane, which was in agreement with a non-chain radical mechanism.

The thermal decomposition of liquid nitromethane has been studied under approximately 4.05 MPa (40 atm) pressure and over the temperature range of 585–613 K (312–340 °C), and shown to be approximately first order with a rate constant given by [241]:

$$k = 10^{13.73} \exp(-49200/RT) \text{ s}^{-1}$$

The main decomposition products were nitric oxide, hydrogen cyanide, carbon dioxide, formaldehyde, and water, with some carbon monoxide and small quantities of methane and nitrous oxide. In addition to this, a solid of the empirical formula $\text{C}_{10}\text{H}_{10}\text{N}_4\text{O}_2$ accumulated as the reaction proceeded. The amount of hydrogen cyanide produced was found to depend on the initial pressure. The initial step in the decomposition was considered to be the same as in the low-pressure range:

The effect of pressure on the rates of decomposition of nitromethane was measured at pressures up to 1.1 GPa [242]. The mechanisms of thermolysis were inferred from kinetic studies and product composition analysis. The rate-controlling step for nitromethane decomposition in toluene at 503 K (230 °C) at low pressures was homolysis of the C–N bond. Beyond 20% conversion, the decomposition was autocatalytic. At high pressure, nitromethane had another reaction path which supplanted homolysis. It was proposed that nitromethane then forms an intermediate by cyclization of its *aci*-form. The high-pressure process was characterized by a first-order rate law without primary kinetic isotope effect, a low activation energy (119.2 kJ/mol = 28.5 kcal/mol), a negative activation volume (–5.5 mL/mol) and formation of products which could not be attributed to radical intermediates. At high conversion, the reaction became autocatalytic as a result of accumulation of water. 2-Nitropropane which was also tested was less stable than nitromethane. The decomposition pathways of nitroalkanes in aprotic solvents are determined not only by the conditions but also by the availability of α -hydrogen.

The decomposition mechanism of hot liquid nitromethane at various compressions was modeled using reactive force field molecular dynamic simulations [243]. A competition between two different initial thermal decomposition schemes was observed, depending on pressure: At low densities, unimolecular C–N bond cleavage was the dominant route, producing $\cdot\text{CH}_3$ and $\cdot\text{NO}_2$ fragments. As density and pressure rose approaching the C–J detonation conditions (~30% compression, >2500 K) the dominant mechanism switched to the formation of the CH_3NO fragment via H-transfer and/or N–O bond rupture. The change in the decomposition mechanism of hot liquid nitromethane leads to a different kinetic and energetic behavior, as well as different products distribution.

3.3.5 Rapid Thermal Decomposition of Liquid Nitromethane

Shock compression of liquid nitromethane is a thoroughly studied initiation mechanism leading to detonation of nitromethane. Chemical changes occurring in liquid nitromethane during rapid compression and leading to initiation of detonation can be traced by rapid spectrophotometric methods, both in absorption and emission spectra. Observation of light emission during excitation and initiation and propagation of detonation of nitromethane is a very useful diagnostic method and several publications referenced in this chapter deal with this method. Because there are so many publications dealing with optical observation of detonating nitromethane, we were almost ready to assign a dedicated heading to a sub-section on optical diagnostic methods, but then decided to integrate it with the rapid thermal decomposition topic at hand. Rapid compression of diluted nitromethane vapors in a shock tube is a widely used method to study the kinetics of rapid decomposition at different shock compression ratios and temperatures. Shock tube decomposition of nitromethane vapors will be discussed in a following section.

The light from detonation of some explosives is suppressed under pressure from an externally produced shock wave. Similar behavior was observed in nitromethane where the homogeneous liquid can be considered to be free of voids, which may interfere with the emitted light [244]. A somewhat more indirect experiment has been described wherein a detonating nitromethane charge was observed normal to the direction of travel of the compression wave. With under-energetic boosting, weak light emission was observed which, after an induction time, suddenly changed to the normal detonation light intensity. The weak light was attributed to predetonation of material compressed by the initiating shock wave.

The emission radiation spectra of a detonation front in nitromethane in the area of 3800–8000 Å were obtained on a spectrograph of average dispersion [245, 246]. The spectra were continuous with no lines or molecular bands. Preliminary measurements have shown that the distribution of energy in the spectrum differs from that predicted by the Planck theorem.

The effects of pressure and temperature on the melting point and thermal decomposition rate were studied using a diamond anvil cell in conjunction with an optical polarizing microscope for melting point observation and an automated FTIR for thermal decomposition monitoring [247–249]. The nitromethane decomposition rate has a positive pressure dependence, leading to a bimolecular reaction mechanism that results from increased intermolecular interactions. Both pressure and temperature were found to increase the rate of thermal decomposition. The mechanism was very complex and varied over large changes in pressure but appeared to be a bimolecular reaction mechanism. A mechanism was proposed which explained the bimolecular nature of the reaction and also accounted for the observed pressure dependence of the decomposition rate and products.

Time-resolved UV-visible absorption spectroscopy was used to examine chemical decomposition in neat liquid nitromethane subjected to stepwise shock loading

to 19 GPa [155]. Up to a peak pressure (temperature) of 13.8 GPa (854 K), no sign of chemical reaction was observed in the absorption band centered at 270 nm. For shock compression resulting in peak temperatures above 940 K, extensive reaction was indicated by irreversible red-shift of the absorption band edge that occurred after peak pressure was reached. This red-shift was followed by a loss of transmission through the sample, which was attributed to the formation of absorbing reaction products. In a series of similar tests, time-resolved Raman spectroscopy instead of UV-visible absorption spectroscopy was used to examine chemical decomposition in neat liquid nitromethane subjected to stepwise shock loading to 14–17 GPa [250]. After a peak pressure at 14 GPa was reached, no changes in the CN (917 cm^{-1}), NO_2 (1400 cm^{-1}), and CH_3 (2968 cm^{-1}) symmetric stretching modes were observed. After a peak pressure at 16 GPa was reached, time-dependent changes were observed during the induction period reported in previous absorption experiments. At this peak pressure, the extent of reaction was small, and the observed changes in the CH_3 and CN modes indicated prereaction changes in the sample bulk. The broadening of the CH_3 peak and the softening of the CN mode observed in this work suggested strong intermolecular interactions. These interactions led to a reaction precursor involving proposed head-to-tail intermolecular associations with decomposition proposed to follow through a bimolecular reaction.

The mechanism of amine sensitization of shocked nitromethane was investigated using time-resolved optical absorption spectroscopy in the visible range [251]. Neat nitromethane and mixtures of nitromethane with six different primary, secondary, tertiary, and di-amines were shocked to within 12–17 GPa peak pressure using step wave loading. Despite the small amine concentrations, profound differences were observed in the absorption spectra of neat and sensitized nitromethane. The changes in the absorption spectrum of reacting neat nitromethane consisted of irreversible broad band (450–650 nm) loss of transmission through the sample after a short induction time. The intermediate is most likely a radical anion of nitromethane, $\text{CH}_3\text{NO}_2^{\bullet-}$.

Time-resolved emission spectra were obtained from neat and ethylenediamine-sensitized nitromethane shocked to 12–17 GPa peak pressures using step wave loading [252]. Broad band emission identified as chemiluminescence from nitrogen dioxide was observed due to reactions in both neat and amine-sensitized nitromethane. When laser light at 514 nm was present, fluorescence in addition to chemiluminescence was observed in shocked nitromethane/ethylenediamine mixtures, but no such fluorescence was found in neat nitromethane. The fluorescing species were assigned to an intermediate formed in the first stage of decomposition in nitromethane/ethylenediamine mixtures, possibly a radical anion of nitromethane, $^{\bullet}\text{CH}_3\text{NO}_2^-$.

At the borderline between low-velocity detonation (LVD) and high-velocity detonation (HVD), the transition from mechanical shock to detonation and the transition from deflagration to detonation (DDT) is of interest. Ultrafast spectroscopic methods by spectral analysis in the range 0.3–0.85 μm can resolve the chemical and physical processes occurring at the front of the shock wave. Experiments used plane shock im-

pact on explosive targets at 8.6 GPa. Shocked nitromethane remained transparent and its temperature was higher than 2500 K because of local chemical reactions [253].

A spectral analysis in the range 0.3–0.85 μm , with a 28-nm resolution, during experiments of plane shock impacts on nitromethane targets at 8.6 GPa was made to study the shock-to-detonation transition of liquid nitromethane [254]. The time-resolved radiant spectra showed that the detonation front, the reaction products produced during the superdetonation and the detonation products were semitransparent. The temperature and absorption coefficient profiles were determined from the measured spectra. Shocked nitromethane reached at least 2500 K, showing the existence of local chemical reactions after shock entrance. The temperature of superdetonation and steady-state detonation can be determined in this way.

3.3.5.1 Computer Modeling of Thermal Decomposition of Nitromethane

Computational chemistry can predict not only properties of the stagnant molecules, but also excited molecules in predissociative states and reactive intermediates. The thermal decomposition of nitromethane is important for its use as a monopropellant or to predict the threshold of thermal explosions. The thermal decomposition starts at the weakest link in the molecule. This section contains references to computer modeling of slow and fast decomposition and to detonation of nitromethane.

Quantum mechanical model calculations for photodissociation of CH_3NO_2 assumed dissociation along the C–N axis with the molecule being restricted to a flexed angular geometry [255]. In addition, the internal degrees of freedom of CH_3 were assumed frozen. The photofragmentation rate as a function of the total energy showed sharp IR band structures and oscillations associated with the existence of a barrier in the dissociative potential energy surface.

Ab initio calculations on predissociative energy levels in nitromethane showed the multi-configurational nature of the ground and first excited singlet states [256]. The potential surfaces relative to the C–N bond lengths showed that each of the excited states studied is strongly predissociative. The results were compared to picosecond UV photolysis experiments in terms of the calculated potential surfaces and the primary photoreaction leading to electronically excited nitrogen dioxide and methyl radicals.

Classical trajectories were used to investigate the unimolecular decomposition of nitromethane on three model potential energy surfaces [257]. The surfaces differed mainly in the barrier height for the isomerization of nitromethane to methyl nitrite. The energies at the barrier to isomerization for the 3 surfaces were assumed as 905, 230, and 199 kJ/mol (216.4, 55.1, and 47.6 kcal/mol). Three primary decomposition pathways were observed:

where * designates an excited state. The dynamic results also showed that there were two mechanisms for isomerization of nitromethane to methyl nitrite. Isomerization via the dissociation-recombination mechanism occurred only on the surface with a large barrier height ($905 \text{ kJ/mol} = 216.4 \text{ kcal/mol}$) that prevented direct isomerization.

In a study of the decomposition mechanism of nitromethane, using the Bond-Additivity-Corrected Moller-Plesset 4th-order perturbation (BAC-MP4) method and extending previous work with calculated rate constants, a detailed reaction mechanism for nitromethane ignition and decomposition was developed [258, 259]. Unimolecular bond fission was believed to be the initial decomposition step to provide a source of CH_3 and NO_2 radicals for the gas-phase reactions. The C—N bond dissociation activation energy for nitromethane was calculated to be 246 kJ/mol (58.9 kcal/mol). The reactions involved in the first-stage ignition process were essentially thermoneutral, yielding very little temperature rise, with the majority of the heat release occurring in the second-stage ignition, which converted NO to N_2 . The ignition delay times ranged from several nanoseconds to tens of microseconds.

The fully optimized potential energy curves for the unimolecular decomposition of the lowest singlet and triplet states of nitromethane through the C— NO_2 bond dissociation pathway were calculated using various DFT and high-level *ab initio* electronic structure methods [260]. Calculation results demonstrated that the triplet state of nitromethane is bound (not dissociated). The adiabatic curve of this state exhibited a 33 kcal/mol energy barrier. Other DFT methods located this barrier at a shorter C—N bond distance with 12–16 kcal/mol lower energy than a multi-configuration self-consistent field method.

The complex potential energy surface for the unimolecular isomerization and dissociation of nitromethane, including 10 isomers, 46 interconversion transition states and 16 major dissociation products was probed theoretically [261]. The geometries and relative energies for various stationary points were determined and were in good agreement with available experimental values. It was shown that the most feasible decomposition channels for CH_3NO_2 unimolecular decomposition were those that lead to $2\text{CH}_3 + 2\text{NO}_2$, $2\text{CH}_3\text{O} + 2\text{NO}$, $\text{H}_2\text{CO} + \text{HNO}$, and $\text{HCNO} + \text{H}_2\text{O}$. Among them, 2CH_3 and 2NO_2 were predicted to be produced by the direct C—N bond rupture of nitromethane, while the formation of the latter three products is most likely initiated by CH_3NO_2 rearranging first to methyl nitrite or to *aci*-nitromethane. The C—N bond dissociation energy for nitromethane was calculated to be 259 kJ/mol (61.9 kcal/mol), lower than the nitromethane $\rightarrow$ methyl nitrite and nitromethane $\rightarrow$ *aci*-nitromethane isomerization barriers by 11.3 and 8.8 kJ/mol (2.7 and 2.1 kcal/mol), respectively. The CH_3NO_2 isomerization pathways seem to be kinetically disfavored in view of the relatively high activation barriers in excess of 251 kJ/mol (60 kcal/mol). The nitromethane decomposition occurred either via the C—N bond rupture or via concerted molecular eliminations.

Density functional molecular dynamic simulations to determine the early chemical events of hot ($T = 3000 \text{ K}$) and dense ($\rho = 1.97 \text{ g/cm}^3$, $V/V_0 = 0.68$) nitromethane showed that the first step in the decomposition process is an intermolecular proton

abstraction mechanism that leads to the formation of $\text{CH}_3\text{NO}_2\text{H}^+$ and the *aci*-ion H_2CNO_2^- [262]. An intramolecular hydrogen transfer that transforms nitromethane into the *aci*-acid form, $\text{CH}_2\text{NO}_2\text{H}$, accompanies this event. The decomposition mechanism was followed up to the formation of H_2O as the first stable product.

Detonation theories for homogeneous, condensed energetic materials have focused on one-dimensional analysis in which the detonation ignition physics is the most difficult part. The classical models consider detonation ignition through a frozen shock transition followed by an induction period, in which the shock temperature induces vibrational, rotational, and electronic excitation followed by molecular dissociation (i.e., thermal decomposition). The frozen shock assumption has been the topic of debate and an alternative model has been proposed whereby detonation ignition arises from excitation of translational degrees of freedom in the shock front. *Ab initio* molecular dynamic simulations of nitromethane under shock initiation conditions offer an alternative approach to elucidate possible mechanisms of detonation ignition [263]. Molecular dynamic simulations of bimolecular collisions using density functional theories serve as a most simplified model for shock-induced dissociation, while multi-molecular collisions including neighborhood molecules serve as a simple model for shock dissociation in bulk liquids.

Ab initio molecular dynamic simulations indicated that during rapid thermal decomposition, solid nitromethane undergoes multiple chemical reactions at about 2200 K under ambient pressure [264]. The initiation of reactions involved both proton transfer and commonly known C–N bond cleavage. About 75 species and 100 elementary reactions were observed with the final products being H_2O , CO_2 , N_2 , and CNCNC .

A global potential energy surface for nitromethane based on fitting density functional theory electronic energies gave a permutationally invariant fit to these energies [265]. Properties of the potential energy surface and quasi-classical trajectory calculations led to a roaming isomerization pathway to the CH_3ONO isomer and then to the $\text{CH}_3\text{O} + \text{NO}$ products. Theoretical and experimental translational energy distribution and rotational energy distributions in the products $\text{CH}_3\text{O} + \text{NO}$ from the unimolecular dissociation of nitromethane were compared to one another [266]. Calculations on a global potential energy surface revealed the detailed roaming isomerization dynamics in this process, and these were supported by experimental observations. Calculations found production of vibrationally excited CH_3O , which was consistent with experiments. This continues to challenge the conventional idea in transition state theory of a localized transition state that was considered a cornerstone of chemical reaction theory.

The kinetics for the thermal unimolecular decomposition of CH_3NO_2 and its structural isomer CH_3ONO have been investigated by statistical theory calculations based on a potential energy surface, including product branching [267]. The results showed that for the decomposition of CH_3NO_2 at pressures less than 2 Torr, isomerization to CH_3ONO via the roaming transition state is dominant in the entire temperature range

studied, 400–3000 K; however, at higher pressures the formation of the commonly assumed products $\text{CH}_3 + \text{NO}_2$, becomes competitive and at pressures higher than 200 Torr the production of $\text{CH}_3 + \text{NO}_2$ is exclusive. The predicted rate constants for 760 Torr and the high-pressure limit with Ar as diluent in the temperature range 500–3000 K, producing solely $\text{CH}_3 + \text{NO}_2$, can be expressed by

$$k_{d760}(\text{CH}_3\text{NO}_2) = 2.94 \times 10^{55} T - 12.6 \exp(-35500/T) \text{ s}^{-1}$$

and

$$k_{d\infty}(\text{CH}_3\text{NO}_2) = 5.88 \times 10^{24} T - 2.35 \exp(-31400/T) \text{ s}^{-1}$$

In the low-pressure regime, the decomposition reaction takes place exclusively via internally excited CH_3ONO , giving rise to both $\text{CH}_3\text{O} + \text{NO}$ and $\text{CH}_2\text{O} + \text{HNO}$ with the second-order rate constant

$$k_{d0}(\text{CH}_3\text{NO}_2) = 1.17 \times 10^{31} T - 10.94 \exp(-32400/T) \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

For CH_3ONO decomposition, a roaming transition state connecting to the $\text{CH}_2\text{O} + \text{HNO}$ products has been located, lying 28.4 kJ/mol (6.8 kcal/mol) below the well-known four-member ring tight transition state and 2.9 kJ/mol (0.7 kcal/mol) below $\text{CH}_3\text{O} + \text{NO}$. The rate constants predicted by similar calculations gave rise to the following expressions for the thermal decomposition of CH_3ONO in He:

$$k_{d760}(\text{CH}_3\text{ONO}) = 8.75 \times 10^{41} T - 8.97 \exp(-22600/T) \text{ s}^{-1}$$

and

$$k_{d\infty}(\text{CH}_3\text{ONO}) = 1.58 \times 10^{23} T - 2.18 \exp(-21100/T) \text{ s}^{-1}$$

in the temperature range 300–3000 K. These results were in very good agreement with available experimental data obtained under practical pressure conditions. The branching ratios for the formation of $\text{CH}_3\text{O} + \text{NO}$ and $\text{CH}_2\text{O} + \text{HNO}$ in the decomposition of both CH_3NO_2 and CH_3ONO are different.

The thermal decomposition of nitromethane provides a classical example of the competition between roaming-mediated isomerization and simple bond fission. Laser schlieren densitometry was used to explore the variation in the effect of roaming on the density gradients for CH_3NO_2 decomposition in a shock tube for pressures of 30, 60, and 120 Torr at temperatures ranging from 1200 to 1860 K [268]. A complementary theoretical analysis provided an exploration of the effects of roaming on the thermal decomposition kinetics. The analysis focused on the roaming dynamics in a reduced dimensional space consisting of the rigid body motions of the CH_3 and NO_2 radicals. A high-level reduced-dimensionality potential energy surface was developed from fits to large-scale multi-reference *ab initio* calculations. The theoretical predictions were compared with prior theoretical predictions, with a related statistical model, and with the extant experimental data for the decomposition of CH_3NO_2 , and for the reaction of CH_3 with NO_2 .

3.3.5.2 Kinetics and Initiation of the Detonation of Nitromethane

The detonation of nitromethane is of practical interest for more than one reason. The main concern is the inadvertent accidental detonation of nitromethane in railroad tank cars. The other area of interest is in the use of nitromethane as a liquid explosive. Nitromethane can be used as a propellant in pulsed detonation engines and rotating detonation engines, which is another reason why detonation of nitromethane is discussed here from both a theoretical and experimental point of view.

It was attempted to identify the rate-determining steps in the ignition of shocked, condensed nitromethane by theoretical calculations [269, 270]. The time t_{pv} required for activation of the internal modes with values of $t_{pv} < 1 \mu s$ were identified with the most efficient transfer of energy when the molecules interact and react bimolecularly in a head-to-tail configuration. These times were consistent with those found in shock experiments and those calculated by other techniques. A minimum pressure of 58 kbar is required for the initiation of high-velocity detonation of homogeneous nitromethane.

A time-of-flight mass spectroscopic study of the chemical reaction zone in base-sensitized detonating liquid nitromethane revealed mass spectra of the reaction zone region for cases where normal CH_3NO_2 and isotope-labeled forms of nitromethane, $^{13}CH_3NO_2$ and CD_3NO_2 , were detonated [271]. The detonation process was initiated by a slapper detonator system. The nitromethane explosives were confined in steel, and the charge geometry was chosen such that the detonations were traveling steadily by the time the detonation wave reached the end of the charge. For the base-sensitized nitromethane explosive, the steady two-dimensional chemical reaction zone was ca. $50 \mu m$ in spatial extent and had a time duration of ca. 7 ns.

The processes involved in the shock initiation of detonation in nitromethane have been the subject of many experimental and theoretical studies. These generally support the classical homogeneous model, although some details of the pressure build-up process are still controversial. In order to clarify these points, plate impact experiments were performed to study the initiation of nitromethane detonation under conditions of steady one-dimensional strain for shock pressures ranging from 8.5 to 12 GPa [272]. The experimental results confirmed the main steps of the classical homogeneous model, but also showed that the build-up process is more complex than previously assumed.

Bimolecular and higher interactions during the initiation of nitromethane are impossible. The most widespread concepts of the primary steps of this initiation, i.e. formation of *aci*-nitromethane anion $[CH_2=NO_2]^-$ by intermolecular hydrogen transfer in the neat nitromethane submitted to shock and formation of this anion by action of an amine, have been scrutinized by a dynamic field theory computational method and evaluated as thermodynamically disadvantageous [273]. Also, the 1,3-intramolecular hydrogen shift in the nitromethane molecule was characterized as a higher barrier process. Two other favorable primary mechanisms of fission in the nitromethane initiation and propagation of its detonation were investigated by calculations: homolysis

of the C—NO₂ bond in neat nitromethane and homolysis of the N—OH bond in its *aci*-form. The second pathway was found to be the thermodynamically most preferable mechanism of fission.

3.3.5.3 Shock Tube Decomposition of Nitromethane Vapor

Although the kinetics of nitromethane vapor decomposition in shock tubes have been studied for a very long time and one would think that all there is to know about nitromethane decomposition has by now been discovered, this topic continues to attract researchers, as indicated by the recent date from some of the publications.

The decomposition of nitromethane in shock waves was followed by spectroscopic observation of the γ system of NO at 2200–2400 Å in a shock tube at temperatures above 1200 K and mixtures consisting of argon and 1.5–10% nitromethane [274]. Initial pressures were 1.3–6.6 kPa (10–50 mm Hg). The kinetic rate equations could not be extrapolated from low temperatures to high temperatures and vice versa, which indicated that different mechanisms were at work.

The thermal decomposition of nitromethane highly diluted in Ar has been studied in shock tubes at $900 < T < 1500$ K and $1.5 \times 10^{-5} < [\text{Ar}] < 3.5 \times 10^{-4}$ mol/cm³ [58]. Concentration/time profiles of unreacted nitromethane and reaction product NO₂ were recorded. The unimolecular first-order reaction was found to be in its fall-off range. Limiting low pressure rate constants of

$$k_0 = [\text{Ar}] \times 10^{17.1} \exp(-42 \text{ kcal/mol}/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

in the range $900 < T < 1400$ K and limiting high pressure rate constants of

$$k_\infty = 10^{16.25} \exp(-(58.5 \pm 0.5 \text{ kcal/mol})/RT) \text{ s}^{-1}$$

have been derived. A rate constant of $1.3 \times 10^{13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ was found for the first subsequent reaction

The decomposition of nitromethane in a shock tube was studied by using a frequency-stabilized CW CO laser to measure the real-time production of NO and CO, two of the key decomposition products [275]. Highly diluted CH₃NO₂/Ar mixtures (0.15–0.75% CH₃NO₂) were used in incident shock experiments over the temperature range from 940 to 1520 K and pressure range from 40 to 101 kPa (0.4–1.0 atm). A mechanism consisting of 37 chemical reactions was used to model the formation of these two products over the entire range of experimental conditions employed. The NO profiles could be quantitatively modeled over the entire temperature range, whereas those of CO could be accounted for only by adjusting some values of the rate constants.

A detailed chemical mechanism describing ignition of high-temperature pure gaseous nitromethane was compiled and tested in a shock tube in the range 1000–1600 K and 1–10 atm [276, 277]. Measurements were made of the time evolution of the pressure at the end wall as well as of the simultaneous pressure and NO

absorption at a short, fixed distance from the end wall. Mass and IR spectroscopy were used to identify the final products. In the reaction mechanism proposed, initiation started with the C—N bond breaking, which yielded $\cdot\text{CH}_3$ and $\cdot\text{NO}_2$. Methoxy and $\cdot\text{CH}_2\text{NO}_2$ radicals then propagate the reaction through two major parallel pathways, both producing CH_2O . Formaldehyde is then reduced to HCO and carries the reaction towards completion. A detailed mechanism of 48 reactions was developed, and calculated induction times showed good agreement with measured values. It was assumed that initiation started with C—N bond breaking with an E_a of 176 kJ/mol (42 kcal/mol), although a fit of the calculated times yielded a global Arrhenius parameter of 162 kJ/mol (38.6 kcal/mol). After the initial decomposition, the reaction takes two major parallel pathways to CH_2O through methoxy $\text{CH}_3\text{O}\cdot$ and $\cdot\text{CH}_2\text{NO}_2$ radicals. The reaction of $\cdot\text{NO}_2$ with $\cdot\text{H}$ was found to be key in generating highly reactive $\cdot\text{OH}$ radicals. The calculations showed that the nitro radical is the key to explosion: $\cdot\text{NO}_2$ produces $\cdot\text{OH}$ through its reaction with $\cdot\text{H}$ radicals. Hydroxyl reactions, which are fast and exothermic, lead to an accelerated consumption of the explosive with heat release. Comparison with the experiments showed that the mechanism predicted correct induction times for the pressure and temperature range of the experiments.

The thermal decomposition of nitromethane was studied spectrophotometrically in incident and reflected shock waves at temperatures in the range 1050–1400 K at total pressures of 0.2–40 atm [278, 279]. Ar, He, CO_2 , and CF_4 were used as collision partners. Under the experimental conditions used, the thermal decomposition of nitromethane occurred in the fall-off region. The pressure dependence of the rate constants was derived from the data. The rate constants in the low-pressure $k_{d,0}$ and high-pressure $k_{d,\infty}$ limits were represented by the following expressions (the activation energy is given here in kJ/mol)

$$k_{d,0(\text{Ar})} = 10^{17.3} \exp(-175.7/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

$$k_{d,\infty} = 10^{16.2} \exp(-249.8/RT) \text{ s}^{-1}.$$

Ignition delay times of exploding nitromethane/oxygen/argon mixtures behind reflected shock waves in a 24-mm diameter, 2.7-m length shock tube but the operating pressure was not stated [280].

The decomposition of nitromethane was measured over the temperature range 1000–1100 K in reflected shock waves and undecomposed CH_3NO_2 and the reaction products were analyzed by gas chromatography (GC) [281]. The derived gross rate constant and activation energy for the disappearance of CH_3NO_2 was consistent with literature data. A reaction mechanism consisting of 99 chemical reactions was developed to simulate the experimental data. Good agreement between experiments and simulations was achieved. It appeared that significant amounts of CH_3NO_2 were destroyed through secondary reactions that involved highly reactive free radicals ($\cdot\text{H}$, $\cdot\text{OH}$, and $\cdot\text{CH}_3$), suggesting the need for redetermining the true unimolecular decay

rate constant for CH_3NO_2 . The loss of nitromethane due to pyrolysis was measured by recording its UV absorption, with a beam directed axially along a small-diameter shock tube.

A re-evaluation of the thermal decomposition mechanisms of gaseous nitromethane and methyl nitrite, where for each system a much simplified mechanism was developed, and the fragmentation/reaction sequence leading to the final products was made more transparent, showed that free radicals ($\cdot\text{CH}_3$, $\cdot\text{H}$, $\cdot\text{OH}$, $\text{HCO}\cdot$, $\text{HNO}\cdot$, $\text{CH}_3\text{O}\cdot$, etc.) played critical roles at different stages of these pyrolysis reactions [282]. A comparison of the products generated by nitromethane with those produced by methyl nitrite showed that the contribution of a nitro-nitrite isomerization reaction in the nitromethane pyrolysis was negligible.

The thermal decomposition of nitromethane under highly diluted conditions in shock tubes has been analyzed in terms of a detailed chemical kinetic model [283]. The experimental data which were adopted from the literature covered the temperature range 1000–1400 K and pressures from 0.5 to 6.0 bar. Based on these experimental results from other sources, rate constants for the reactions

and

have been re-examined. The high and low pressure limits for reaction (R1) determined by others have been shown to be consistent with more recent shock tube data. A reinterpretation of the shock tube results together with room temperature measurements indicated that the rate constant for (R14) decreased slightly with temperature, as $k_{14} = 4.0 \times 10^{13} T^{-0.2} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$. At high temperatures and atmospheric pressure this reaction was more than an order of magnitude faster than recombination of $\cdot\text{CH}_3$ and $\cdot\text{NO}_2$ to form nitromethane. Based on the available data for the forward and reverse rates of reaction (R1), a value of $279 \pm 8.4 \text{ J mol}^{-1} \text{ K}^{-1}$ ($66.7 \pm 2.0 \text{ cal mol}^{-1} \text{ K}^{-1}$) for the entropy S_0^{298} of CH_3NO_2 was estimated.

The kinetics of nitromethane decomposition and the rate constant of the process were measured behind reflected shock waves using absorption spectroscopy at $\lambda = 230 \text{ nm}$, temperatures of 1060–1350 K, pressure of $\sim 40 \text{ atm}$, and initial reactant concentrations within 30–100 ppm [284]. It was observed that at the initial stage, nitromethane decomposed exponentially without autoacceleration. The results of numerical simulations with the help of three most known kinetic schemes of nitromethane decomposition were in close agreement with experimental data over the entire temperature range covered. It was demonstrated that the measured rate constant was identical to the rate constant of the dissociation reaction

The temperature dependence of k_1 was approximated by the Arrhenius equation

$$k_1 = 2.57 \times 10^{14} \exp(-52.85/RT) \text{ s}^{-1}$$

where the activation energy is in kcal/mol, which suggested that the nitromethane dissociation proceeds in the fall-off pressure region. In a similar later study, the temperature dependence of k_1 was expressed by the Arrhenius equation

$$k_1(\text{NO}_2) = (6.3 \pm 2) \times 10^{12} \exp(-48.9 \pm 2/RT) \text{ s}^{-1}$$

where the activation energy again is in kcal/mol [285].

Ignition delay times of nitromethane ignition behind reflected shock waves were measured using the chemiluminescence emission from the $A^2\Sigma^+ \rightarrow X^2\Pi$ transition of the excited-state hydroxyl radical (OH^*) in a stainless steel shock tube [286]. The driver section was 2.46 m long (76-mm i. d.), and the driven section was 4.72 m long (152-mm i. d.). Post-reflected shock conditions were obtained using the extrapolated incident shock wave speed in conjunction with shock relations and the initial conditions in the test region. Wide ranges of conditions were investigated in terms of temperature (875–1595 K), pressure (1.8–34.3 atm), equivalence ratio ($\phi = 0.5, 1.0$, and 2.0) and dilution (99, 98, 95, and 90% Ar). Increasing ϕ led to an increase in t_{ign} at around 1420 K, t_{ign} was increased by a factor >3 when ϕ was doubled, from 0.5 (135 μs) to 1.0 (450 μs). For additional shock tube experiments, see also [287, 288].

3.3.6 Photodissociation (Photolysis) of Nitromethane

Nitromethane would normally be stored in the dark. Storage in clear containers in direct sunlight may induce photolytic decomposition. Nitromethane vapors that escaped from storage or nitromethane formed from pollutants in the atmosphere is photolyzed by sunlight. Laser photolysis of nitromethane may be useful to initiate controlled decomposition of nitromethane in a rocket engine, in particular those operating in pulse mode with multiple starts. Photolysis of unreacted nitromethane ahead of the detonation wave, caused by radiation emanating from the combustion zone, may be a predissociation step that presensitizes nitromethane to the subsequent detonation. Laser beams may be used to detect traces of nitro compounds in areas where they do not belong and where they might cause harm.

The photolysis of nitromethane in a matrix of solid argon at 20 K gives methyl nitrite [289]. All other products can be explained in terms of the secondary photolysis of methyl nitrite. The primary products of photolysis of methyl nitrite under these conditions are formaldehyde and nitroxyl, HNO .

The photolysis and pyrolysis of nitromethane and methyl nitrite have been studied by flash photolysis and kinetic spectroscopy [290]. The results showed that photolysis of nitromethane yields methyl radicals and nitrogen dioxide, and that these fragments undergo recombination and disproportionation reactions to form methyl nitrite, methoxyl, and nitric oxide. In the presence of added nitric oxide the methyl

radicals reacted principally with nitric oxide to form nitrosomethane, which subsequently dimerized and also reacted further with nitric oxide to yield nitrogen dioxide. Light absorption by methyl nitrite resulted not only in photolysis, but also in the formation of an isomer of the nitrite, which then reverted slowly to the stable form.

Photolysis of nitromethane in gas phase at 313 nm was studied at 328 K (55 °C) [291]. Methyl nitrite, formaldehyde, nitrosomethane, and NO were obtained as main products, their quantum yields were $\phi_{\text{CH}_3\text{ONO}} = 0.22$, $\phi_{\text{HCHO}} = 0.20$, $\phi_{\text{CH}_3\text{NO}} = 0.06$, and $\phi_{\text{NO}} = 0.10$. The dependence of the quantum yields on the pressure of quenching gases such as ethylene or NO were investigated. The quantum yield of triplet nitromethane was determined and compared with that by product analysis. Both gave the identical value: 0.6. Since ϕ_{HCHO} was not affected by any quencher, it was concluded that formaldehyde was formed directly from singlet excited nitromethane.

The dissociation of nitromethane following the excitation of the $\pi^* \leftarrow \pi$ transition at 193 nm has been investigated by two independent and complementary techniques: product emission spectroscopy and molecular beam photofragment translational energy spectroscopy [292]. The primary process was shown to be cleavage of the C–N bond to yield $\cdot\text{CH}_3 + \cdot\text{NO}_2$ radicals. The translational energy distribution for this chemical process indicated that there are two distinct mechanisms by which $\cdot\text{CH}_3 + \cdot\text{NO}_2$ radicals are produced. The dominant mechanism releasing a relatively large fraction of the total available energy to translation probably gives $\cdot\text{NO}_2$ radicals in a vibrationally excited 2B_2 state.

Atmospheric photodissociation rate coefficients and photodissociation lifetimes for nitromethane were calculated as a function of altitude from their measured visible and near ultraviolet photoabsorption cross-sections at 298 K [293]. From 0 to 50 km the lifetime of nitromethane varies from 10 to 0.5 h, while that of the more abundant methyl nitrate changes from 5.3 to 0.09 days.

The cross-section for photodissociation of nitromethane at 193 nm is $(1.7 \pm 1.0) \times 10^{-17} \text{ cm}^2$. From this it was inferred that the quantum yield for the process is nearly unity [294]. Photofragments of the dissociation were observed at masses 15, 16, and 30 corresponding to CH_3 , O, and NO, but only a very small number of fragments at mass 46 (NO_2) was measured. Time-of-flight spectra were obtained for all fragments except for mass 46. The data can be explained by assuming that two sequential absorptions of photons occur. The first photon dissociates CH_3NO_2 to CH_3 and NO_2 . The second photon is absorbed by the NO_2 fragment to give $\text{NO} + \text{O}$. About 30% of the NO_2 participate in the second absorption and the rate determining step is the primary absorption.

Photodissociation of nitromethane at 266 nm under collision-free conditions resulted in the single photon production of electronic ground state $\text{OH}(X^2\Pi_j)$ [295]. A rotational “temperature” of $1750 \pm 50 \text{ K}$ can describe the rotational distribution of the nascent OH radical. The quantum yield for the photolytic pathway producing the OH radical was 0.004 ± 0.001 .

It appears that UV irradiation of nitromethane produces the *aci*-form which is more susceptible to detonation than the regular form [296]. The activating effect of UV irradiation is similar to the addition of organic amines: both produce the *aci*-anion which is responsible for rapid detonation of nitromethane [297].

Laser-induced fluorescence of decomposing nitromethane vapors can be used as a sensitive analytical method to detect nitromethane vapors in air, for instance in the vicinity of improvised explosive devices. The system used a pulsed laser beam to photolyze molecules of a nitromethane vapor sample introduced into a vacuum chamber [298]. Emission fluorescence of the fragments produced by photodissociation by excimer laser photolysis of nitromethane at 193 nm could be quantified and calibrated. The principal fragment emission occurred at 431 nm.

Polarized emission spectra from photodissociating nitromethane excited at 200 and 218 nm showed a strong progression in the NO₂ symmetric stretch [153]. At 200 nm a weak progression in the NO₂ symmetric stretch in combination with one quantum in the C—N stretch also contributed to the spectra. Measurements of the angular distribution of emitted photons in the strong emission features from the relative intensity ratio between photons detected perpendicular to *versus* along the direction of the electric vector of the excitation laser showed anisotropy. The anisotropy was substantially reduced from the 2 : 1 ratio expected for the pure CH₃NO₂ transition with no rotation of the molecular frame. The intensity ratios for the features in the NO₂ symmetric stretching progression were near 1.5–1.6 for 200 nm excitation and 1.7 for 218 nm excitation. The analysis of the photon angular distribution measurements and consideration of the absorption spectrum indicated that the timescale of the dissociation was too fast for molecular rotation to contribute significantly to the observed reduction in anisotropy. It was suggested that a reassignment of the minor dissociation channel, first evidenced in photofragment velocity analysis experiments which detected a pathway producing slow CH₃ fragments, to the near threshold dissociation channel $\bullet\text{CH}_3 + \bullet\text{NO}_2(^2\text{B}_2)$ should be made.

Multi-photon ionization spectroscopy and time-of-flight mass spectrometry have been used to determine nascent photofragment energy distributions for several of the products of the 193 nm photolysis of nitromethane [299]. Internal energy distributions have been obtained for CH₃ and NO, and translational energy distributions for CH₃, NO and O(³P). The production of two NO electronic states (*X* and *A*) and the appearance of two peaks in the translational energy distributions of the CH₃ and O fragments are consistent with a two-channel dissociation. The major channel produced CH₃ and NO₂(²B₂), some of the latter having sufficient internal excitation to further dissociate to NO and O. The minor channel is believed to produce NO₂ in a different electronic state, which subsequently absorbs a second 193 nm photon and dissociates to yield NO and O.

The direct photolysis of liquid nitromethane was observed after pulse excitation at 299 nm using a sub-picosecond coherent anti-Stokes Raman spectroscopy (CARS)

instrument [300]. From the dynamic behavior under excitation of three main ground-state Raman lines it was deduced that the excited state disappeared with a lifetime of 1.1 ps and a photolysis quantum yield at 299 nm of 24%.

The photochemistry of nitromethane has been studied extensively for many years. Although it is generally agreed that the principal photodissociative process is cleavage of the C–N bond to yield the methyl radical and nitrogen dioxide, there is some evidence of minor competing dissociation channels. Femtosecond laser pulses have been used as a diagnostic method to study multi-photon ionization and photodissociation of nitromethane and led to the efficient production of intact molecular ions [301]. Femtosecond laser mass spectrometry (FLMS) could provide added information on the dissociation pathways of nitromethane. Laser pulses of 90 fs time duration at wavelengths of 375 and 750 nm, coupled to a time-of-flight mass spectrometer have been used and contrary to photoexcitation using nanosecond (ns) pulses, a large parent ion, 61 (CH_3NO_2^+), was detected together with strong peaks at $m/e = 15(\text{CH}_3^+)$, 30 (NO^+), 46 (NO_2^+) as well as a number of other minor peaks. This fragmentation pattern can be explained by a predominant ionization followed by dissociation route.

The isotope-selective IR multi-photon dissociation of nitromethane molecules in the region of stretching vibrations of the NO_2 group with IR free-electron-laser irradiation in a mixture with the natural content of the ^{15}N isotope of 0.4% showed that the content of the ^{15}N isotope in the products of NO dissociation was dependent on and varied within 0.1–1.6% as a function of the laser radiation frequency [302].

The dynamics of oxygen atom formation in the gas-phase photolysis of nitromethane was studied using the pulsed laser photolysis/laser-induced fluorescence (LIF) pump-and-probe technique [303]. Room temperature CH_3NO_2 vapor molecules were excited at 2 UV photodissociation laser wavelengths of 248 and 266 nm. Nascent O photofragments were detected via LIF in the vacuum UV spectral region under collision-free conditions. Narrow-band probe laser light, tunable over the wavelength range 130.2–130.6 nm, was used to monitor the fine-structure state distribution of nascent O atom product. The quantum yields for O atom formation were $\phi(\text{O}) = 0.18 \pm 0.03$ at 248 nm and $\phi(\text{O}) = 0.13 \pm 0.04$ at 266 nm.

The relevant low-lying singlet and triplet potential energy surfaces in the photolysis of nitromethane were studied by using the multi-state extension of the multi-configurational second-order perturbation theory in conjunction with large atomic natural orbital type basis sets [304]. The proposed mechanism for the photolytic decomposition of CH_3NO_2 provided a consistent and re-interpreted picture of the available experimental results. Two reaction paths were found in the photolysis of nitromethane after excitation at 193 nm. No ionic species were predicted in any dissociation path. The low-lying Rydberg states of nitromethane and nitrogen dioxide were then compared since both are present in the reacting mixture.

The photodissociation dynamics of nitromethane starting at the S(3) excited state has been studied at the complete active space self-consistent field level of theory in

conjunction with atomic natural orbital type basis sets [305]. The energies of all the critical points and the energy profiles connecting them have been recomputed with a multi-configurational second-order perturbation method. It was found that the key step in the reaction mechanism is a radiationless decay through an S(3)S(2) conical intersection.

Measurements of the nascent $\bullet\text{OH}$ product from photodissociation of nitromethane and nitroethane vapor at 266 nm were performed using the single-photon laser-induced fluorescence technique [306]. The $\bullet\text{OH}$ fragment was found to be vibrationally cold for both systems.

Photodissociation of nitromethane has been investigated for decades both theoretically and experimentally; however, the dissociation dynamics for nitromethane were still disputed for decades, although many different mechanisms have been proposed. To make a revised interpretation of these different mechanisms, photolysis of nitromethane at 226 and 271 nm under both collisional and collision-free conditions was investigated at nanosecond and femtosecond time scales [307]. These two laser wavelengths correspond to the $\pi^* \leftarrow \pi$ and $\pi^* \leftarrow n$ excitations of nitromethane, respectively. In nanosecond 226 nm ($\pi^* \leftarrow \pi$) photolysis experiments, CH_3 and NO radicals were observed as major products employing resonance-enhanced multi-photon ionization techniques and time-of-flight mass spectrometry. A few OH and CH_3O radicals were observed as dissociation products employing laser-induced fluorescence spectroscopy. The CH_3O product was only observed under collisional conditions. In femtosecond 226 nm experiments, CH_3 , NO_2 , and NO products are observed. These results confirmed that rupture of the C—N bond should be the main primary process for the photolysis of nitromethane after the $\pi^* \leftarrow \pi$ excitation at 226 nm, and the NO_2 molecule should be the precursor of the observed NO product. Formation of the CH_3O radical after the recombination of CH_3 and NO_2 species under collisional conditions ruled out a nitro-nitrite isomerization mechanism for the generation of CH_3O and NO from $\pi\pi^*\text{CH}_3\text{NO}_2$. Combined with the 271 nm nanosecond pump-probe experiments, in which none of the CH_3 , NO_2 , CH_3O or OH fragments were observed, it was suggested that all the fragment ions generated in 271 nm femtosecond laser experiments were derived from the parent ion, and dissociation of nitromethane from the $n\pi^*$ excited electronic state does not occur in a supersonic molecular beam under collision-free conditions.

A primary dissociation reaction takes place at 193 nm

Total cross-sections and asymmetry parameters for single-photon ionization from the highest occupied molecular orbitals of nitromethane were computed with a single-channel, frozen-core approximation for photon energies between 0.5 and 20 eV [308]. One-electron resonant processes in the ionization channels and recoil frame photoelectron angular distributions were studied based on a local model potential.

The photodissociation dynamics of nitromethane, following photoabsorption at 213 nm in the $\pi^* \leftarrow \pi$ transition, have been studied using ion imaging [309]. The state-resolved velocity and angular distributions were measured for the CH_3 , NO, and O atom fragments. The CH_3 velocity distribution consisted of two peaks with different angular distributions. The slow and fast components showed isotropic and anisotropic distributions, respectively. The NO and O fragments also showed slow components with isotropic angular distributions. The results observed consistently indicated that these slow photofragments were possibly produced by a concerted three-body dissociation channel.

The photodissociation of nitromethane at 193 nm was reviewed in terms of stereodynamic information provided by the measurement of the first four Dixon's bipolar moments using slice imaging [310]. The measurements indicated that after one-photon absorption by an allowed perpendicular transition, two reaction pathways can compete with similar probability, a direct dissociation process yielding ground-state CH_3 and $\text{NO}_2(1^2\text{A}_2)$ radicals and an indirect dissociation through conical intersections in which NO_2 radicals are formed in lower-lying electronic states. The low recoil energy part of the methyl fragment translational energy distribution presents a contribution with parallel character, irrespective of the experimental conditions employed that was attributed to parent cluster dissociation.

The techniques of infrared multi-photon dissociation (IRMPD) and state selective ion imaging were combined to probe roaming dynamics in the unimolecular dissociation of nitromethane and methyl nitrite [311]. Theoretical calculations suggested a roaming-mediated isomerization pathway of nitromethane to methyl nitrite prior to decomposition. State-resolved imaging of the NO product coupled with infrared multi-photon dissociation was carried out to examine this unimolecular decomposition near the threshold. The IRMPD images for the NO product from nitromethane were consistent with the earlier IRMPD studies that first suggested the importance of an isomerization pathway. The experimental observations were compared to the results of parallel quasi-classical trajectory calculations for nitromethane and methyl nitrite. The observation of distinct methoxy vibrational excitation for trajectories from nitromethane and methyl nitrite dissociation at the same total energy showed that the nitromethane dissociation bears a non-statistical signature of the roaming isomerization pathway, and this is possibly responsible for the nitromethane Λ -doublet propensity as well.

Photodissociation pathways of nitromethane following $\pi \rightarrow \pi^*$ electronic excitation via the potential energy surfaces for four lowest singlet states, and structures of many intermediates, dissociation limits, transition states and minimum energy conical intersections were determined using an automated searching algorithm [312]. Geometries were finally optimized and energies were computed. The calculated preferable pathways and important products were able to qualitatively explain most experimental observations. The major photodissociation products CH_3 and $\text{NO}_2(^2\text{B}_2)$ are formed by direct dissociation from the S_1 state. Important

pathways involving S_1 and S_0 states for production of various dissociation products $\text{CH}_3\text{NO} + \text{O}(^1\text{D})$, $\text{CH}_3\text{O}(\text{X}^2\text{E}) + \text{NO}(\text{X}^2\Pi)$, $\text{CH}_2\text{NO} + \text{OH}$, and $\text{CH}_2\text{O} + \text{HNO}$, as well as various isomerization pathways have been identified. Three roaming processes also have been identified: the O atom roaming in O dissociation from CH_3NO_2 , the OH radical roaming in OH dissociation from $\text{CH}_2\text{N}(\text{O})(\text{OH})$, and the NO roaming in NO dissociation from CH_3ONO .

Solid nitromethane along with its isotopically labeled isotopologue D_3 -nitromethane (CD_3NO_2) ices were exposed to Lyman α photons from a hydrogen discharge lamp to investigate the mechanism involved in the decomposition of energetic materials in the condensed phase [313]. The chemical processes in the ices were monitored online and *in situ* via IR spectroscopy complimented by temperature programmed desorption studies utilizing highly sensitive reflectron time-of-flight mass spectrometry coupled with pulsed photoionization at 10.49 eV. The IR data revealed the formation of *cis*-methyl nitrite (CH_3ONO), formaldehyde, water, carbon monoxide, and carbon dioxide. Upon sublimation of the irradiated samples, three classes of higher molecular weight products, which are uniquely formed in the condensed phase, were identified: **(1)** nitroso compounds, nitrosomethane (CH_3NO), nitrosoethane ($\text{C}_2\text{H}_5\text{NO}$), nitrosopropane ($\text{C}_3\text{H}_7\text{NO}$), **(2)** nitrite compounds, methyl nitrite (CH_3ONO), ethyl nitrite ($\text{C}_2\text{H}_5\text{ONO}$), propyl nitrite ($\text{C}_3\text{H}_7\text{ONO}$), and **(3)** higher molecular weight molecules, $\text{CH}_3\text{NONOCH}_3$, $\text{CH}_3\text{NONO}_2\text{CH}_3$, $\text{CH}_3\text{OCH}_2\text{NO}_2$, and $\text{ONCH}_2\text{CH}_2\text{NO}_2$. The decomposition of nitromethane in the condensed phase is more complex compared to the gas phase under collision-free conditions opening up not only hitherto unobserved decomposition pathways of nitromethane (hydrogen atom loss, oxygen atom loss, retro carbene insertion), but also the blocking of several initial decomposition steps. Similar tests were later performed using fast electrons instead of ultraviolet light. See also [314, 315].

3.3.7 Electron Bombardment of Nitromethane

Electron bombardment of nitromethane takes place in the inlet portion of mass spectrometers. The appearance potential of decomposition products is an indication of the stability of the molecule. The adiabatic electron affinity of nitromethane is 0.50 ± 0.02 eV and the C–N bond dissociation energy is 2.67 ± 0.1 eV. For nitromethane, the calculated bond dissociation energy is $D(\text{CH}) = 4.42$ eV, electron affinity is $\text{EA}(\text{CH}_2\text{NO}_2) = 2.45$ eV, and gas-phase acidity is $\text{GPA} = 15.4$ eV [316, 317].

Nitromethane has a positive adiabatic electron affinity. Photoelectron measurements led to a value of 0.26 ± 0.08 eV. Dissociative electron attachment in nitromethane and its anionic states has been investigated using optical and electron scattering methods [318]. The nature and dissociation dynamics of the low-lying anionic states of nitromethane were explained in the light of these experiments and compared to results of *ab initio* molecular orbital computations and qualitative,

simplified potential energy diagrams of energy vs. C—N bond length. It seems that despite the complexity of the dynamics and the large excess of energy, the processes following electron capture by nitromethane are not statistical. Excited anionic states have been probed mostly through dissociative electron attachment processes such as

Dissociative electron attachment measurements to nitromethane in the gas phase have been made by use of a high mass-resolution sector field mass spectrometer [319, 320]. Anion efficiency curves for 16 negatively charged fragments were measured in the electron energy region from about 0 to 16 eV with an energy resolution of ~1 eV. Eight previously unseen anions have been detected: CH_2NO_2^- , CHNO_2^- , CH_2NO^- , H_2NO^- , CH_3^- , CH_2^- , CH^- , and H^- . The five most dominant product anions were NO_2^- , O^- , OH^- , CN^- , and CNO^- , all of them featuring two high-energy resonances at about 5 and 10 eV. Formation of CH_2NO_2^- at low electron energies has been explained in terms of dissociative electron attachment to highly vibrationally excited molecules.

Low energy electron-induced dissociation in multi-layer films of deuterated nitromethane (CD_3NO_2) was investigated by high resolution electron energy loss spectroscopy (HREELS) and by the electron stimulated desorption (ESD) of neutral species [321]. The HREELS measurements showed that the lowest electronic states of the condensed molecule are very similar to those seen in the gas phase. Desorbed neutrals were detected using combined non-resonant multi-photon ionization at 355 nm and time-of-flight mass spectrometry. The most intense signals detected were those of CD_3^+ and NO^+ and were attributed primarily to the desorption of CD_3 and NO_2 fragments following molecular dissociation via low-lying electronic excited states of nitromethane. By varying the time delay between the incident electron pulse and the ionizing laser pulse, it was possible to measure the kinetic energy distributions of desorbing fragments. The kinetic energy distributions above ~5 eV appeared invariant with incident electron energy, indicating that the same desorption process (dissociation via low-lying electronic states) operates at all the studied incident energies. At energies less than ~5 eV, contributions from dissociative electron attachment were also observed in the yield of CD_3 and other neutral fragments.

Icy films of nitromethane or its isotopologue D_3 -nitromethane (CD_3NO_2) were exposed to ionizing radiation (instead of Lyman α line UV light as above) to investigate the mechanisms in the decomposition of (D_3)-nitromethane [322]. The radiation-induced modification of the ices was followed during the radiation exposure *in situ* via IR spectroscopy (condensed phase) and via temperature-programmed desorption (TPD) exploiting reflectron time-of-flight mass spectrometry joined with single photon ionization of the subliming molecules at 10.49 eV (gas phase). The IR spectroscopic and kinetic studies revealed the formation of methyl nitrite via isomerization of nitromethane as well as the presence of formaldehyde, nitrosyl hydride (HNO), and radical decomposition pathways (forming methoxy radical CH_3O and nitrogen monoxide NO), altogether accounting for about 85% of all products formed. The TPD studies

with time-of-flight mass spectroscopy revealed three classes of complex molecules: (i) nitroso compounds, (ii) nitrites and (iii) higher molecular weight products with the synthesis of the homologue series of nitroso and nitrite compounds likely governed by a stepwise molecular growth via carbene (CH_2) insertion. Three decomposition pathways of solid nitromethane were identified, which do not take place in the gas phase: (i) the fragmentation of nitromethane to the nitromethyl radical (CH_2NO_2) plus suprathreshold atomic hydrogen (H), (ii) formation of nitrosomethane (CH_3NO) plus atomic oxygen (O), and (iii) generation of singlet carbene (CH_2) plus nitrous acid (HONO).

Thin films of homogeneously mixed normal nitromethane (CH_3NO_2) and D_3 -nitromethane (CD_3NO_2) frozen ices were exposed to energetic electrons and Lyman α UV photons [323]. The isotopically mixed reaction products were probed *in situ* via time-of-flight mass spectrometry coupled with pulsed photoionization during temperature programmed desorption, providing information on three high energy decomposition pathways, which had not been previously observed under collision-free conditions in the gas phase. These were (1) decomposition of nitromethane via atomic oxygen loss to nitrosomethane (CH_3NO), (2) fragmentation of nitromethane and/or methyl nitrite (CH_3ONO) via carbene (CH_2) loss, (3) and C–H bond rupture processes in nitromethane and/or methyl nitrite.

Absolute dissociative ionization cross-sections of nitromethane from threshold to 200 eV have been measured using Fourier transform mass spectrometry [324]. In the production of positive ions by electron impact ionization 13 ions were detected, including the parent ion CH_3NO_2^+ and the 4 most important fragment ions CH_3NO^+ , NO_2^+ , NO^+ , and CH_3^+ . In the production of negative ions by dissociative electron attachment to nitromethane, three anions were detected: CH_2NO_2^- , NO_2^- , and CN^- .

3.3.8 Radiolysis of Nitromethane

It is unlikely that nitromethane would ever be used as a rocket propellant in outer space on long-term missions, where it would be exposed to cosmic radiation that triggers decomposition. The radiolysis of nitromethane produces free radicals that promote decomposition, similar to photolysis, but under more controlled, selective conditions than during thermal decomposition. The same free radicals observed during radiolysis also play a role in the thermal decomposition of nitromethane [325–327].

Initial 100-eV radiolysis yields and effects of dose on the rates of formation of 12 products of the ^{60}Co γ -ray-induced decomposition of pure, air-free, liquid nitromethane have been measured at constant dose rate ($9 \times 10^{17} \text{ eV g}^{-1} \text{ min}^{-1}$) at 273 K (0 °C) and at room temperature. The *cis*-dimer of nitrosomethane, methyl nitrite, and formaldehyde were the major initial products [328]. Mechanisms now identified in the radiolysis of nitromethane may be the same as those occurring in the radiolysis of other commercially more important nitro compounds.

3.3.9 Oxidation of Nitromethane

The reaction of nitromethane vapor with oxygen has been studied in the temperature range from 700 to 740 K in a constant volume, static vessel outside the explosion limit [329]. The explosion limit was markedly lowered due to addition of oxygen, when compared with the case of nitromethane alone and was determined as a function of temperature and/or of O₂ concentration. A simulation of the 121-step “simplified mechanism” gave results that seemed to match experimental data well, not only for the oxidation of nitromethane but also for its pyrolysis, provided that a new way of formation of HCN was introduced. The simulations allowed an estimation of the order of magnitude of several rate constants, the values of which were not precisely known. For example, the rate constant of the reaction

may be about 2.4×10^{11} – 3.0×10^{11} cm³ mol⁻¹ s⁻¹ in the temperature range 700–740 K.

3.3.10 Analytical Methods for Nitromethane

Nitromethane that is to be used as a solvent for electrochemical or spectrophotometric measurements must be purified of contaminants commonly introduced during its manufacture. Apart from water, which is easily removed by distillation down to concentrations near 0.001M owing to the formation of a water-nitromethane azeotrope ($t_b = 356\text{ K} = 83^\circ\text{C}$ at 1 atm), nitromethane contains relatively high concentrations of homologues, which have little effect on the chemical properties of the solvent but which lower its density and raise its viscosity. Different concentrations of the homologues undoubtedly caused the large variations in density (1.1230–1.13124 g/cm³) and viscosity (6.08–6.275 mPa s) reported by various authors. The best method for purification of nitromethane is crystallization from a solution in diethyl ether at low temperatures [92]. This paper also contains a good summary of physical properties of pure nitromethane. Contaminants commonly found include not only nitroethane and 2-nitropropane at concentrations near 0.1M, but also propionitrile at concentrations near 0.1M.

3.3.10.1 Analysis of Bulk Nitromethane

Samples were taken at random from 60 barrels of nitromethane which had been stored at Yuma Proving Grounds in Arizona under varying environmental conditions and sent to Southwest Research Institute for analyses by atomic absorption, mass spectroscopy, gas chromatography, and FTIR [330]. The nitromethane content was determined along with contaminant analyses for nitroethane, 2-nitropropane, water, and metals. The results showed: nitromethane >98%, nitroethane <1.1%, 2-nitropropane <0.2%, water <0.11, and metals <10 ppb.

3.3.10.2 Analysis of Nitromethane in the Air

Nitromethane is quite volatile and vapor pressure may cause hazardous concentrations to build up in areas where work is done with nitromethane. The air in workspaces needs to be monitored to make sure the concentration is below the Threshold Limit Value-Time Weighted Average (TLV-TWA) [331]. Laser-induced fluorescence of decomposing nitromethane vapors can be used as a sensitive analytical method to detect nitromethane vapors in air, for instance in the vicinity of improvised explosive devices. An experimental system used pulsed laser beam photofragment molecules of a nitromethane vapor sample introduced into a vacuum chamber [298]. Emission fluorescence of the fragments produced by photodissociation by excimer laser photolysis of nitromethane at 193 nm can be quantified and calibrated. The principal fragment emission occurred at 431 nm. The limit of detection for nitromethane was 1.6×10^8 molecules, corresponding to an interrogated sample volume of 0.0375 cm^3 and a chamber pressure of $1.3 \times 10^{-7} \text{ mm Hg}$ (i.e., a concentration of 4.2×10^9 molecules/ cm^3). The linear dynamic range extended over 3.5 decades in nitromethane pressure (relative standard deviation of less than 4%).

The acquisition of an analyte from the atmosphere by a nebulization process and electrochemical detection of nitromethane used a gold screen-printed electrode in a flow-thru cell where a detection limit of $4.5 \mu\text{M}$ was achieved and it was selective toward nitromethane amidst a large panel of interfering compounds. Square wave voltammetry was used for this purpose with a gold working electrode and a phosphate buffer at pH 7.5. The limits of detection were $2.3 \mu\text{M}$ without dissolved oxygen in the solution and $12.5 \mu\text{M}$ in air [332, 333]. Detection times of less than 1 min were obtained for nitromethane contents of 8 and 90 ppm.

Nitromethane, nitrobenzene, and some nitro-rich triazole derivatives vapors in air can be detected using a pulsed photoacoustic technique [334]. UV light at 266 nm wavelength i.e. fourth harmonic of Q-switched Nd:YAG laser having pulse durations of 7 ns and 10 Hz repetition rate was used to record the time-resolved photoacoustic spectrum. The photoacoustic fingerprint was produced due to absorption of incident UV light by the molecule itself and photodissociation of nitromethane.

3.4 Strand Burning of Nitromethane

Strand burning of nitromethane and other nitro and nitrate compounds will be discussed in the monopropellant section in *Encyclopedia of Monopropellants*, chapter “Organic Monopropellants”, in connection with rocket engines using such propellants. Nitromethane is underoxidized but it is unlikely to be used as a fuel in bipropellant rocket engines. Combustion of nitromethane in an oxidizing atmosphere will be discussed in a future *Encyclopedia of Non-hypergolic Bipropellant Combinations*.

3.5 Storage Stability of Nitromethane

At higher temperatures, at 322K (49°C) and above, nitromethane undergoes a slow decomposition with evolution of nitrogen dioxide. Therefore, storage temperatures this high should be avoided. According to some sources, the thermal stability can be improved by adding boric acid, hydroquinone, sulfuric acid, or phosphoric acid.

3.6 Materials of Construction for Nitromethane

Nitromethane can be stored in containers made of many common materials of construction. In metals, in the presence of moisture, the rate of corrosion may be accelerated because nitromethane exists in two tautomeric forms, of which the *aci*-form is the more corrosive. The rates of corrosion were measured in stainless steel 0.0025 mm/year, aluminum 0.0025 mm/year and copper 0.0076 mm/year [169]. Stainless steel is a specific catalyst for the decomposition of nitromethane and increased the reaction rate 40-fold [221].

3.7 Handling of Nitromethane

3.7.1 Equipment for Handling of Nitromethane

It was recommended to use slowly closing, non-steel valves in nitromethane systems to prevent water hammer effects and rapid compression of entrained bubbles which might lead to explosions [335].

3.8 Accident History of Nitromethane

For a long time nitromethane was considered safe enough to be shipped all over the United States in railroad tank cars and tanker trucks. That changed dramatically in 1958 when two explosions occurred in two separate incidents with railroad tank cars holding 37000 L of nitromethane [336, 337].

One explosion occurred in a railroad switching yard near Niagara Falls, NY, on 22 January 1958, causing 200 injuries. A rail tank car containing 35 tons of nitromethane detonated, forming a crater 15 × 26 m (50 × 85 ft) wide and 4.8 m (16 ft) deep. Damage extended out to 4.8 km (3 miles) from the explosion center.

The second explosion of 43 tons of nitromethane occurred near Mt. Pulaski, IL on 1 June 1958, and caused 2 fatalities and 4 injuries. The material damage amounted to several million dollars (1958 dollars). The crater was 12 m deep and had a diameter of 30 m [338].

A nearly empty drum of nitromethane exploded at a facility of Dynamit Nobel in Germany in May 1989. In another part of the world, experiments were performed in an effort to determine the cause of an explosion that occurred during a nitromethane manufacturing and rectification process in China [339]. Test samples were collected from the accident site and analyzed by GC and DSC, including reaction product, crude product, 99% pure product and raffinate. A sample evaporating experiment recorded the reaction phenomena occurring at low liquid level in the sump of the still. Based on the experimental results, excess heat released by the decomposition of overheated raffinate was pinpointed as the most likely cause of the explosion.

3.9 Toxicity of Nitromethane

Because nitromethane is finding widespread application as a paint solvent, the vapor toxicity has been thoroughly investigated, in particular after it became apparent that nitromethane is a human (not only an animal) carcinogen. Although nitromethane has not found application as a rocket propellant, its toxic properties are reviewed here because they are related to the toxicity of other more energetic nitro compounds that are used as plasticizers in rocket propellants.

A detailed summary of various aspects of the toxicity of nitromethane has been published as a monograph chapter by the International Agency for Research on Cancer (IARC) [340]. The toxicity of nitromethane is distinctly different from the toxicity of the aromatic nitro compound, nitrobenzene. Absorption of nitromethane into the body leads to the formation of methemoglobin which in sufficient concentration causes cyanosis. The onset of symptoms may be delayed for 2–4 h or longer after ingestion. Table 30 is a summary of lethal dose and lethal concentrations of nitromethane determined in animal exposure tests.

Rabbits and guinea pigs (2 of each species) survived exposures to 30000 ppm for 15 min or 10000 ppm for 1 h, but all died when exposed to 30000 ppm for 2 h or 10000 ppm for 6 h. In a short-term subchronic study, a monkey exposed to 1000 ppm nitromethane in air died after 8 daily 6-h exposure periods. At 500 ppm, the lowest concentration used in this study, 2 rabbits, and 1 monkey survived a total exposure period of 140 h (administered in daily 6-h periods).

Rats exposed to 13000 ppm nitromethane in air died after 6 h [341]. At 2500 ppm, rats survived 4 consecutive 6 h/day exposures but died on the fifth day.

In a study for NIOSH [342], groups of rats and rabbits were exposed to air containing 98 or 745 ppm of nitromethane for 7 h/day, 5 days/week, for periods up to 24 weeks. Groups of 10 rats were sacrificed after 2, 10 days, and 1, 3, and 6 months of exposure. All animals survived the exposure at both concentrations and only mild to moderate symptoms of toxicity were observed in the rats and rabbits. Effects of nitromethane exposure were: decreased weight gain in rats following 8 weeks of exposure to 745 ppm

Table 30: Toxicity of nitromethane based on animal exposure tests.

Route	Species	Dose, mg/kg	Response
Oral	Rats	1210	LD50
Oral	Rats	940	LD50
Oral	Mice	1440	LD50
Oral	Mice	950	LD50
i.p.	Mice	110	LD50
Oral	Rabbits	750	LDLo
Oral	Dogs	125	LDLo
s. c.	Dogs	565	LDLo
i. v.	Rabbits	750–1000	LD50
i. v.	Dogs	800	LDLo
Inhalation	Monkeys	1000 ppm	LCLo
Inhalation	Monkeys	980 ppm	LCLo

Data sources: [83, 84]

and a thyroid effect in rabbits that was indicated by increased thyroid weight and decreased serum thyroxin levels. No exposure-related gross or microscopic alterations were found in any of the tissues examined in the rats and rabbits exposed to either 98 or 745 ppm nitromethane.

Chronic exposure tests of animals to low levels of nitromethane vapor in air extended for over 2 years showed significantly increased frequency of tumors in liver tumors. The results are summarized in Table 31.

Table 31: Chronic exposure animal inhalation test results with nitromethane.

Animal	Concentration, ppm	Frequency	Duration
Rat	188	6h/day	2 years
Mouse	750	6h/day	2 years

Groups of rats were housed in inhalation chambers and exposed to vapors of nitromethane at either 100 or 200 ppm for 7 h/day, 5 days/week for 2 years [343]. The animals were observed daily for signs of pharmacologic or toxic effects and body weights were recorded periodically. At the 2-year termination of the exposure period, serum chemistry and hematology tests were performed on selected animals and all surviving animals were sacrificed. All animals were necropsied and subjected to a thorough histopathologic examination. During the study there were no pharmacologic effects from exposure to nitromethane at either 100 or 200 ppm. There was no effect on mortality at either exposure level. There was no effect of exposure of rats to either level of nitromethane on hematology. There were no clinically significant

effects on serum chemistry. There were no effects of exposure to nitromethane on organ weights. There were no significant differences in the non-neoplastic or neoplastic pathology related to exposure to nitromethane.

Although nitromethane is not expected to be a contaminant in the atmosphere of crewed spacecraft, the National Aeronautics and Space Administration (NASA) has compiled a 20-page summary with 20 literature references of the toxicity considerations for nitromethane should it inadvertently find its way into space station atmospheres by an undefined and unexpected pathway [344]. Toxicity topics summarized include lethality, symptoms, thyroid toxicity, hematological changes, pulmonary toxicity, effects on reproductive function, carcinogenesis, and genotoxicity. The Spacecraft Maximum Allowable Concentration was set at 25 ppm for 1 h and 5 ppm for 180 days.

Toxicology and carcinogenicity studies were conducted by inhalation administration of nitromethane to groups of 50 F344/N rats of each sex at exposures of 0, 94, 188 or 375 ppm and 50 B6C3F1 mice of each sex at exposures of 0, 188, 375 or 750 ppm for 6 h/day, 5 days/week, for 103 weeks [345]. Under the conditions of these 2-year inhalation studies, there was no evidence of carcinogenic activity of nitromethane in male F344/N rats exposed to 94, 188 or 375 ppm. There was clear evidence of carcinogenic activity of nitromethane in female F344/N rats based on increased incidences of mammary gland fibroadenomas and carcinomas. There was clear evidence of carcinogenic activity of nitromethane in male B6C3F1 mice on increased incidences of Harderian gland adenomas and carcinomas. There was clear evidence of carcinogenic activity in female B6C3F1 mice, based on increased incidences of liver neoplasms (primarily adenomas) and Harderian gland adenomas and carcinomas. Increased incidences of alveolar/bronchiolar adenomas and carcinomas in male and female mice exposed to nitromethane were also related to chemical administration. Exposure to nitromethane by inhalation for 2 years resulted in increased incidences of nasal lesions including degeneration and metaplasia of the olfactory epithelium and degeneration of the respiratory epithelium in male and female mice.

The potential of nitromethane to induce morphological transformation in the Syrian hamster embryo cell transformation assay using a 24-h exposure protocol was tested with doses of 2000, 2500, 3000, 3500, and 4000 g/mL [346]. Both the 4000 and the 5000 g/mL dose groups showed a statistically significantly greater increase in morphological transformation frequency compared to the concurrent controls.

The environmental fate and transport processes with spilled nitromethane were reviewed in detail [347]. The fate of nitromethane in water will depend on its ability to undergo chemical, photochemical, and biological reactions, and on partitioning (transport) from the water column into air or sediment. It appeared that the nitroalkanes (including nitromethane) are not hydrolyzed to any measurable extent by the action of water alone. Environmental decay through photolysis is likely to occur, but data concerning photolysis rates in aqueous solution or under environmental wa-

ter conditions could not be found. Nitromethane is fairly reactive and therefore does not persist in the environment. The half-life time of nitromethane is ~4–9 h in air and ~1 day in water. The fate and transport of nitromethane in soil has received very little attention and biodegradation mechanisms are unclear. The relatively high vapor pressure and the high evaporation rate of nitromethane indicated that it may evaporate quite rapidly from dry soil surfaces at a spill site. If nitromethane is spilled into surface water, aquatic toxicity seems to be low. Nitromethane concentrations of 659 ppm were not lethal to fathead minnows (*Pimephales promelas*) over a 96-h exposure, although “severe sublethal effects” were observed. The reportable quantity in cases of a nitromethane spill was set at 1000 lb. For additional information on carcinogenicity and teratogenicity of nitromethane, see [348, 349].

3.9.1 Maximum Allowable Exposure Limits for Nitromethane

Based on animal exposure data, nitromethane has been categorized as a group 2B carcinogen by the IARC Carcinogen List criteria. The recommended exposure limits (REL) are:

- 1993–1994 American Conference of Governmental Industrial Hygienists (ACGIH) TLV: 100 ppm (250 mg/m³) TWA
- 2000 ACGIH TWA 20 ppm
- USA OSHA PEL TWA 8 h/day 100 ppm (250 mg/m³)
- NIOSH REL: The 1989 OSHA PEL may not be protective to workers.
- Original NIOSH (Standards Completion Program, SCP) Immediately Dangerous to Life and Health (IDLH): 1000 ppm

The original NIOSH IDLH was later revised downward to 750 ppm [350, 351]. The chosen IDLH was based on earlier observations that with concentrations above 1000 ppm, if the product of this concentration and the time of exposure was greater than 1 (e.g., 1000 ppm for 3 h) some of the animals, including 1 monkey, had died.

3.10 Safety Properties of Nitromethane

The monopropellant qualities of nitromethane and other nitroalkanes and alkyl nitrates will be discussed in a later volume. The data summarized here deal only with the handling, storage, and transportation safety properties of these compounds.

During a comprehensive search of the literature in order to identify hazards associated with the planned use of nitromethane in the Tactical Explosive System (TEXS), the information was grouped into several categories: adiabatic compression, detonation, tests, change in properties, health hazards and other problems [352]. This is a good source of information for the safe handling of nitromethane.

3.10.1 Transportation Hazard Classification of Nitromethane

Storage and transportation regulations for nitromethane were critically reviewed at a time when the US Army anticipated using larger quantities of this material for a TEXS for minefield clearing. At one time the US Department of Transportation (DOT) and OSHA classified nitromethane only as a flammable liquid. This classification seems to ignore the explosion accidents that have occurred with this material. The US Department of Defense classified nitromethane as a mass-detonating explosive. Liquid nitromethane hazard classification parameters and hazards classification of various slurry mixtures with nitromethane were re-examined in preparation for an anticipated more widespread use of nitromethane in a TEXS [353].

3.10.2 Flash Point and Lower Limit of Flammability

The open cup flash points and the lower limits of flammability in air of nitroalkanes are summarized in Table 32. The upper limits of flammability in air cannot be determined because the vapor is combustible or even detonable all the way to 100% vapor.

Table 32: Flash point and lower limit of flammability of nitroalkanes.

Compound	Open cup flash point		Closed cup flash point		Lower flammable limit in air
	K	°C	K	°C	vol.-%
Nitromethane	317	44	317.6	44.4	7.3 7.3 at 33 °C
Nitroethane	314	41			4.0 3.4 at 30 °C
1-Nitropropane	322	49			2.6 2.2 at 34 °C
2-Nitropropane	311	38			2.6 2.5

Data source: W. R. Grace Datasheet [354]

The autoignition temperature of nitromethane in air is 713 K (440 °C). Other sources give the autoignition temperature as 691 K (418 °C = 785 °F). The flash point by the Abel-Pensky method is 308–310 K (35–37 °C) and its fire point by the Marcusson method is 315–316 K (42–43 °C) [355].

3.10.3 Explosive Sensitivity of Nitromethane

Nitromethane can be used as a rocket propellant or as an explosive, depending on the modes of initiation, the charge geometry, and the presence or absence of sensitizers such as amines, gas bubbles or microballoons. If one uses nitromethane as a rocket propellant, unintended accumulation of unburned nitromethane in the combustion

chamber may lead to explosions. After shutting off an engine at the end of the intended mission, unburned nitromethane in the injector passages, valves, and feed lines may overheat from heat soaking back into the injector and explode. For this reason this book contains a fairly detailed summary of safety and detonation properties of nitromethane.

Nitromethane can be used as the fuel in pulse detonation rocket engines or rotating detonation rocket engines. Sensitivity, detonation velocity, and critical diameter are important properties for evaluating nitromethane as a propellant for these applications. This is one of the reasons why nitromethane explosive properties have been included in such detail in this book. Nitromethane has been considered as a rocket propellant for a long time, but its sometimes unpredictable sensitivity to accidental explosion has prevented any widespread use [356, 357].

The detonation of condensed explosives may not be of similar nature to that of gaseous detonations [358]. Pulsating detonations of condensed and gaseous explosives are similar in nature and are initiated by oblique shock collisions in the detonation wave front [359].

The detonation kinetics and explosion reaction mechanisms in a variety of systems consisting of nitromethane, molecular oxygen, and water vapor were studied using reactive molecular dynamics to simulate reactions in time domain, as they would occur in real life [360]. The high polarity of the nitromethane molecule plays a key role, driving the first exothermic step of the reaction. Rapid temperature and pressure growth stimulate the subsequent reaction steps. Oxygen is important for faster oxidation, whereas its optimal concentration is in agreement with the proposed reaction mechanism. Addition of water (50 mol %) inhibited detonation; however, water did not prevent detonation entirely.

3.10.3.1 Drop Weight Impact Sensitivity of Nitromethane

There are contradicting reports on the drop weight sensitivity of nitromethane in the literature, most likely caused by using a different apparatus or using propellant samples of dubious purity. One source reports that nitromethane did not explode with a 2-kg weight dropped from 1.95 m [361]. Other sources report that dropping a 200-g weight from 20 cm resulted in an event in 20% of the tests, and that a 200-g weight from 40 cm resulted in an event in 90% of the tests [362]. Metal acetylacetonate salts can change the drop weight sensitivity of nitromethane in either direction, cobalt or chromium acetylacetonate increase the sensitivity, whereas copper or nickel acetylacetonate reduce the sensitivity.

Nitromethane or tetranitromethane could not be made to explode under the maximum impact load of the apparatus used when tested for impact sensitivity in comparison to glycerol trinitrate, ethylene glycol dinitrate, and other energetic liquids [363].

The drop weight sensitivity and detonability of nitromethane is reduced by addition of diluents like alcohols (methanol, ethanol, isopropanol) or phlegmatizing ad-

ditives (copper acetylacetonate) [364, 365]. The drop weight impact sensitivity of nitromethane with a 5-kg mass with rebound impact was 160 cm [78].

3.10.3.2 Adiabatic Compression Sensitivity of Nitromethane

One danger associated with the operation of nitromethane rocket engines is that on occasion explosions will occur at the start of a run. This seems to be due to the fact that nitromethane will detonate spontaneously if it is heated to temperatures above $561 \pm 28 \text{ K}$ ($550 \pm 50^\circ \text{ F}$). This heat probably comes from adiabatic compression of gas bubbles [366]. Sudden compression of nitromethane to 18.8 MPa (136 atm) has caused sudden explosions, whereas compression to 9.4 MPa (93 atm) did not trigger any hazardous reactions as long as there were no bubbles in the liquid.

Some of the adiabatic compression sensitivity testing has been done by including a bubble with a known gas filling and a well-defined size. The adiabatic compression sensitivity of nitromethane was tested in an adiabatic compression sensitivity tester developed by Aerojet in comparison to that of *n*-propyl nitrate, methylacetylene and a mixture of 60% ethyl nitrate/40% propyl nitrate [367]. The apparatus consisted of a pneumatically driven piston rapidly compressing a gas bubble above a liquid propellant sample. In a few cases, especially for nitromethane, the apparatus was also inverted, pushing the liquid upward into the gas (vapor) bubble. The sensitivity was

Figure 7: Adiabatic compression sensitivity of nitromethane (republished and modified from [367], with permission of © 1959 American Institute of Aeronautics and Astronautics; permission conveyed through Copyright Clearance Center Inc.)

expressed in terms of the piston kinetic energy divided by the size of the gas bubble, which is the slope of a straight line separating the go-no go areas in an x-y chart (Figure 7). The results are summarized in Table 33. Nitromethane was of intermediate sensitivity in this series of tests.

Table 33: Adiabatic compression sensitivity of nitromethane in comparison to other monopropellants.

Compound	Adiabatic compression sensitivity, kg cm mL ⁻¹
Mixture of 60% ethyl nitrate/40% propyl nitrate	4.0 ± 0.8
<i>n</i> -Propyl nitrate	6.7 ± 1.2
Nitromethane	10.4 ± 1.7
Methylacetylene	86 ± 12

Data source: [367]

Hydrazine, hydrogen peroxide, ethylene oxide or unsymmetrical dimethylhydrazine (UDMH) could not be made to explode at the maximum capable compression rate of this machine (>144 kg cm mL⁻¹). If nitromethane is pushed into a dead-end cavity of a tubing, an explosion will result if the push pressure is 5.88 MPa (58 atm), even if the gas space contains only nitrogen instead of air. See also [368, 369]. Note that in all these tests, not the push pressure, but the pressure rise rate is the important criterion.

“Secondary ignition” was defined as any ignition due to sources other than the desired direct initiation when using nitromethane in rocket engines or explosives dispensing systems.

A study of the shock initiation to detonation transition of nitromethane by itself in the absence of bubbles by a nearly rectangular relatively long-duration, 60-kilobar amplitude shock showed that the time to the appearance of detonation in 3 experiments with shocks of nominal initial pressures of 65, 62, and 60 kilobars was approximately 10, 16, and 20 μs, respectively [370]. Chemical reactions in or near the shock front appeared to accelerate the shock front and reduce the time to initiation.

A series of experiments was conducted in which liquid nitromethane was dynamically compressed to peak pressures in the order of 10 kbar [371]. The compression chamber consisted of a high-strength steel cylinder divided into two compartments by a tightly fitting steel piston. An explosive pressurization charge was placed in one compartment and the sample of nitromethane in the other. The pressure pulse in the nitromethane consisted of a damped oscillation with rise time in the order of 50 s. An initiation and non-detonating decomposition of the nitromethane was repeatedly observed. Diagnostic instrumentation was not sufficiently precise to accurately determine the onset of the decomposition process, but it occurred no later than 200 s after onset of the pressure pulse. Alternative initiation mechanisms were discussed, and it

was shown that initiation by adiabatic compression of air bubbles appears to be the most likely explanation. A theoretical expression for the chemical induction time of nitromethane heated by compressed air bubbles was then derived. The calculations were based on rapid adiabatic compression of air (using a real-gas EOS), a laminar heat conduction process at the gas-liquid interface, and an Arrhenius reaction rate in the decomposing nitromethane.

Adiabatic compression initiation characteristics of liquid propellant nitromethane under dynamic fill conditions in a TEXS were measured in the laboratory and formed the basis for design change recommendations for a nitromethane dispensing system [335]. Nitromethane drawn from four 208-L (55-gallon) barrels was combined in a 833-L (220-gallon) tank for mixing and dispensing. The conditions tested at Princeton Combustion Research Laboratories (PCRL) included:

- Liquid non-bubbly NM
- Liquid nitromethane with fine cavitation bubbles
- Liquid nitromethane with fine air bubbles
- Liquid nitromethane with large air pockets

Calculations were for a 37-mm (1.5-in.) diameter hose with flow rates up to 3780 L/min. (100 gal/min.) Tests were conducted at 293, 328, and 336 K (20, 55, and 63 °C), using the PCRL tester and 2.5 mL in a U-tube test with 6-mm (1/4-in.) O.D. CRES tubes and push pressures up to 9.3 MPa (1350 psi) and cavity pressures up to 103 MPa (15000 psi). The U-section had a radius of 75 mm (3 in.) and the length of the straight section of the dead-end tube was 114 mm (4.5 in.) The PCRL tester achieved pressurization rates of up to 172 MPa/ms (25000 psi/ms).

Spectroscopic methods and rapid-response thermocouples can be used to measure the temperature rise preceding the detonation in shocked nitromethane [372].

The section on *n*-propyl nitrate in chapter “Nitrate Esters” contains a comparison of the adiabatic compression sensitivities of nitromethane, nitroethane, and *n*-propyl nitrate [373]. Nitromethane was the intermediate sensitive liquid of the three liquids tested, with energy required to initiate an explosion in 50% of the tests being between that of nitroethane and *n*-propyl nitrate.

In a U-tube adiabatic compression sensitivity test apparatus with variable, preselected push pressure and constant bubble size, nitromethane could not be made to explode and the push pressure required to explode nitromethane or trinitromethane was beyond the maximum energy input capability of the apparatus, much higher than that of methyl nitrate, glycerol trinitrate, or ethylene glycol dinitrate (EGDN) [374].

3.10.3.3 Bullet Impact Sensitivity of Nitromethane

Bullet impact tests with nitromethane resulted in explosions, but only sporadically. There are too many variables in this test. Under certain conditions (container size, ullage size, wall thickness of 6 mm, container material) nitromethane has been exploded

on impact of 0.50 caliber high-velocity bullets. In similar tests with thin-walled containers (such as 17E drums) no explosions occurred. In the absence of a vapor space above the liquid, it was difficult to achieve detonations even in thick-walled containers.

3.10.3.4 Cap Sensitivity of Nitromethane

Data from an experimental investigation of the shock initiation of liquid nitromethane with shock pressures from 7.5 to 9.5 GPa and temperatures in the unreacted liquid from 900 to 1100 K supported the thermal ignition model of one-dimensional shock initiation of nitromethane [375]. The kinetic parameters in a first-order overall rate law for the initiation-decomposition reaction in nitromethane were

$$k_1 = 2.6 \times 10^9 \exp(-23000/RT) \text{ s}^{-1}$$

which was appreciably different from the rate constant for the unimolecular bond-scission reaction. The data supported the conclusion that radical reactions significantly influence the overall initiation reaction in liquid nitromethane.

The shock and adiabatic compression sensitivity of nitromethane depends largely on the uniformity and gas content of the sample. It is known that inhomogeneities in the form of gas bubbles or suspended solid particles may result in sensitization and sustained LVD. The hot spot theory for propagation of LVD in liquids has been derived in large part from experiments with nitromethane [376, 377]. The optical observations made during the build-up to detonation and the measured shock sensitivities supported a model of initiation for heterogeneous explosives. For studies on the shock initiation of nitromethane explosions, see also [272, 378–383].

3.10.3.5 Card Gap Sensitivity of Nitromethane

Nitromethane has often been used to calibrate test methods for the determination of the sensitivity of liquid explosives; however, its sensitivity depends on the amount of dissolved gases and the eventual addition of sensitizers like amines or hydrazine [384, 385]. Unfortunately, the type and amount of sensitizer has not always been documented in the literature. The card gap sensitivity has been measured in mixtures of nitromethane (gelled with 2% dissolved polymethylmethacrylate, PMMA) with solids as hot spot generators [386]. The detonation velocity of the 2% PMMA/98% nitromethane gel was 6350 m/s. The 50% go-no go point gap width of the 2% PMMA/98% nitromethane gel was 31 mm. See also [387, 388].

3.10.3.6 Shaped Charge Penetration Sensitivity of Nitromethane

It is unlikely that nitromethane tanks in rockets will be penetrated by shaped charge jets, but this may be a special method for initiation and may be similar to meteorite impacts in outer space. This mode of initiation would be more a matter of concern if nitromethane was transported in a military vehicle in hostile territory. It may also be a method for deliberate disposal of surplus or contaminated nitromethane.

The hypervelocity jet initiation threshold criteria for neat nitromethane and homogeneously and heterogeneously sensitized nitromethane mixtures have been determined experimentally over a range of failure diameters, jet velocities from 2–9 mms and different jet diameters in two test configurations [389, 390]. The effect of temperature on failure diameter was measured. These criteria were used to define detonation and failure conditions in nitromethane and the nitromethane mixtures as a function of contact-and bow-shock conditions. A favorable correlation of threshold values was achieved by normalization of the criteria with the failure diameters.

3.10.3.7 Cook-off and Time-to-Explosion Sensitivity of Nitromethane

Thermal explosion times as a function of temperature have been measured for nitromethane, perdeuteronitromethane and 6 dinitroalkanes at 1, 10, and 50 kbar [391]. For a constant thermal explosion time of 30 s, the thermal explosion temperatures were: nitromethane (1 kbar) 627 K = 354 °C, (10 kbar) 551 K = 278 °C, and (50 kbar) 457 K = 184 °C. At 10 kbar and 546 K = 273 °C, the thermal explosion time of perdeuteronitromethane was about 10 times more than that for nitromethane. Using thermal explosion theory, for nitromethane the following Arrhenius parameters were obtained: at 1 kbar, $\log A_s$ ($A_s = A/s^{-1}$) = 40, $E = 531$ kJ (mol = 127 kcal/mol; at 10 kbar, $\log A_s = 5.3$, $E = 92$ kJ/mol = 22 kcal/mol; at 50 kbar, $\log A_s = 6$, $E = 84$ kJ/mol = 20 kcal/mol. At 50 kbar and 498 K = 225 °C the first-order rate constant for nitromethane decomposition was by a factor of more than 10^7 greater than for C–N bond fission.

Thermal explosion times were measured for nitromethane at 50 kbar and for 1,1-dinitropropane, 1,2-dinitropropane and 2,2-dinitropropane at 10 kbar in the temperature range from 423 to 623 K (150–350 °C) [392].

3.11 Explosive Performance of Nitromethane

The primary interest in this book is in nitromethane as a rocket propellant and not in nitromethane as an explosive; however, accidental explosions of nitromethane have occurred when attempting to use it as a rocket propellant, and the conditions leading to unintended initiation of explosion need to be better understood. Most of the publications on detonation of nitromethane referenced here were motivated by the use of nitromethane as an explosive or as a model substance for other explosives. Learning more about the detonation of nitromethane gives us a better understanding of the (often unwanted) detonation of other energetic materials that are used as rocket propellants. Summarizing all publications that have dealt with detonation of nitromethane would fill an entire book in its own right. We are sampling here just a random collection of publications that deal with the detonation of nitromethane, but we probably only scratched the surface of the treasure of information that can be collected if this was the main objective of a literature study. Many of the experiments described

here were done in academic settings and because nitromethane was readily available. Some investigators have failed to provide information if nitromethane was sensitized by chemical additives or not.

In the context of this book, explosions of nitromethane are more likely to be accidental than intentional, but nevertheless we are including at least a tiny fraction of all the literature available on nitromethane as an explosive. Before starting to re-evaluate nitromethane as a rocket propellant, one has to have a thorough understanding of the explosive behavior of nitromethane in order to avoid any unpleasant surprises. Rocket propellant chemists looking for more energetic rocket propellants often are treading a thin line, which is the borderline between a more energetic rocket propellant and a poor explosive. Reading the following sections will give the reader a more solid understanding of where the borderline is.

Sensitized nitromethane can be used as a liquid explosive (the acronym PLX stands for **P**icatinnny **L**iquid **E**Xplosive). The chemical sensitizer used most frequently is ethylene diamine [393, 394], but the disadvantage is that the mixture may segregate into two layers on standing. Mechanical sensitization can be achieved through the use of microballoons, hollow glass spheres or other suspended particles.

Time-resolved vibration spectroscopy with picosecond tunable mid-IR pulses was used to measure the rates and investigate the detailed mechanisms of multi-phonon up-pumping and vibrational cooling in nitromethane [395]. Both processes occurred on the 100 ps time scale under ambient conditions. The mechanisms involved sequential climbing or descending the ladder of molecular vibrations. Efficient intermolecular vibrational energy transfer from various molecules to the symmetric stretching excitation of NO₂ was observed, which helped to understand shock initiation to detonation and the sensitivities of energetic materials to shock initiation.

3.11.1 Detonation of Nitromethane Mixtures

Various additives have been evaluated to reduce the detonation sensitivity of nitromethane to make it safe for transportation and eventual use as a rocket propellant. The additives may or may not prevent the formation of the more sensitive *aci*-form of nitromethane. One of the more thoroughly investigated additives and diluents is methanol because it is used in nitromethane/methanol mixtures as a fuel for model airplane engines.

A ternary nitromethane mixture called NTN consisted of a 5/1/1 mol ratio mixture of nitromethane, tetranitromethane, and 1-nitropropane [396]. It remained liquid over the range 219–347 K (–65 to +165 °F).

Acetone has often been used as a diluent for nitromethane for academic detonation studies to slow down the detonation velocity and make it easier to observe with instruments that cannot handle the higher velocities of undiluted nitromethane [397].

The detonation of nitromethane-tetranitromethane mixtures can propagate at low and high detonation velocities [398].

The effect of acetone, nitroethane or tetrachloromethane on the detonation velocities and critical diameters of nitromethane detonation in brass tubes was tested [399]. Acetone, nitroethane, chloroform, and carbon tetrachloride were mixed with nitromethane and critical diameters in brass tubes were determined for these mixtures at 298 K (25 °C). Detonation velocities at infinite diameter and coefficients of diameter dependence of the detonation velocity were also estimated by applying a least squares method to the values obtained by accurate measurements in various charge diameters. The CJ detonation parameters were calculated and compared with the observed velocities. The lighter the diluent liquid was, the more it affected the critical diameter. Most effective was acetone, least effective was CCl_4 , nitroethane was in between. Nitroethane behaved as if it was an inert liquid on the detonation of nitromethane. The least squares fit of these data gives the following equation for the detonation velocity of nitromethane at 298 K (25 °C):

$$D = 6.2601 - 0.0405 \times (1/\phi)$$

where D is the detonation velocity in km/s and ϕ is the charge diameter in cm. The detonation velocity in infinite diameter of nitromethane would be 6260 ± 5 m/s at 298 K (25 °C) which leads to 6343 ± 5 m/s at 277 K (4 °C). This value was about 30 m/s lower than the value of 6374 m/s reported by other sources.

An experiment was devised to simulate the development of explosive reactions in a large mass of cavitated liquid in which a massive steel piston was propelled into a container (diameter 10 cm) filled with a liquid explosive into which bubbles have been introduced [400]. Most of these substances are usually assessed as “non-detonable” in the card-gap test since they have a critical diameter greater than the diameter in which the card-gap test is normally performed, usually 2.5 cm. In this experiment, transition to “detonation” has resulted using nitromethane and other marginally detonable liquids at initial piston velocities of 24–90 m/s. With further increase in scale size, abrupt accelerations of the order of those occurring in a transport container may suffice to produce explosion. A mathematical model was developed by which the hazard potential of deflagration-to-detonation transition in large masses of a reactive liquid subjected to cavitating conditions and pressure surges can be assessed from burning rate data or from small-scale experiments such as that described. A marginal explosive is any material not intended to be used as an explosive and that cannot be detonated by a No. 8 blasting cap but that is at least theoretically capable of reacting with energy release. The marginally explosive liquid was contained in a steel cylinder of 10.2-cm inside diameter, 15.2-cm length, and 1.27-cm wall thickness. Air bubbles were introduced into the liquid by means of a 15-cm length of polyvinyl chloride tubing which had two rows of pinholes at 21 bars. It was hoped that a correlation could be established between the bubbled detonation hazard and a simple bench-top test measuring the linear strand burning rate (Table 34) but that seemed to be far-fetched.

Table 34: Comparison of nitromethane experimental results with liquid strand burning rates.

Material	Composition	Threshold velocity m/s	Burning rate at 11 MPa cm/s
Nitromethane	100%	24 ± 2	0.27
Amine nitrate aqueous solution	88% ^a	24 ± 6	1.5 ^b
<i>n</i> -Propyl nitrate	100%	91.5 ± 1.5	0.21–0.12
Dinitrotoluene	100%	52.5 ± 4.54	0.29
Nitromethane/1-nitropropane mixture	52/48	~90	0.026
Nitromethane/2-nitropropane mixture	53/47	>119	0.028
Nitromethane/methanol mixture	55/45	>91	0.031

^a Proprietary composition, presumably methylammonium nitrate^b At 7 MPa

Data source: [400]

The effects of dilution of nitromethane with acetone, methanol, nitroethane, nitrobenzene, chloroform, carbon tetrachloride or bromoform on detonation velocities were examined in confined samples [401]. Several of these otherwise inert diluents actually participated in the detonating reaction.

In order to study the influence of oxygen ratio and density on the radiative properties of detonation fronts, brightness temperature measurements have been performed in nitromethane-tetranitromethane mixtures using a four-color pyrometer [402]. The experimental results showed that for the condensed nitromethane-tetranitromethane mixtures the detonation front behaved like a black body. The observed results were compared with calculated ones using several different EOS. The experiments were performed in nitromethane-tetranitromethane mixtures with the following molar proportions: $\text{CH}_3\text{NO}_2 + \alpha\text{C}(\text{NO}_2)_4$ where $\alpha = 0.071, 0.12, 0.25$, and 0.5 . A stoichiometric mixture is obtained for $\alpha = 0.25$ and when reaction partners are in such proportions that $\alpha < 0.15$, the detonation products contain solid carbon which radiated intensely.

The light emitted from the detonation front from nitromethane diluted with acetone is not very bright, and the light amplification available with an image intensifier camera is needed to make sufficiently short exposures possible. Dark waves in the detonation front of nitromethane-acetone mixtures have been photographed using pairs of image intensifier cameras, triggered at slightly different times [403]. The photographs showed the motions and changes of a complex wave structure where the average brightness did not change as much from center to edge as simple theory would predict, showing that the bright regions are high temperature regions, not just areas where less absorbing material is present ahead of the light-emitting layer.

Nitromethane is offered by some commercial nitroalkane producers as a solution in methanol. Detonation tests in mixtures of nitromethane with methanol as an inert (non-explosive) additive in steel tubes of various diameters provided information on the effect of the degree of dilution on detonability [404–406]. Mass velocity pro-

files with a chemical spike characteristic of detonation waves were recorded at the unsteady detonation front in all mixtures studied. This made it possible to distinguish the CJ state and obtain a fairly complete set of detonation parameters. Diluting the explosive with an inert liquid will slow down the detonation and make it possible to observe some of the reactions on an expanded time scale.

The shock wave sensitivity and initiating shock wave pressures of binary mixtures of nitromethane with <38% methanol and <43% nitrobenzene were determined by measurements of particle velocities by an electromagnetic method [407]. The limit initiating pressure dependences on non-explosive liquid content was linear. In both mixtures the dilution of nitromethane with non-explosive components resulted in decreasing shock wave sensitivity.

Historically, dilution of liquid explosives with inert solvents was shown to affect a degradation in the detonation performance properties of any explosive, and result in a rapid increase in the critical diameter with increasing diluent concentration. The results of a series of gas gun-driven plate impact experiments on nitromethane-methanol solutions of several concentrations, using *in situ* electromagnetic gauging to measure the initial shock state (Hugoniot) of the mixture, as well as the overtake-time-to-detonation, surprisingly, showed that the shock sensitivities did not fall off dramatically with increasing methanol concentration [408]. In fact, at some concentrations methanol appeared to sensitize nitromethane, relative to the sensitivity of neat nitromethane.

Addition of hydrazine (or any other base) will increase the sensitivity of nitromethane and addition of methanol will decrease it. It would thus be interesting to identify the point where the sensitization by hydrazine is compensated by dilution with methanol. This can be done experimentally or it can be predicted by computation [409]. An EOS of binary solutions of hydrazine and nitromethane was taking into account a possibility of formation of associated molecules due to interactions between hydrazine and nitromethane molecules. Thermodynamic calculations of detonation parameters of hydrazine-nitromethane binary systems were done for a wide range of hydrazine contents in explosive mixture. (From 0 to 75 mass-%) and for a few ternary (hydrazine-nitromethane-methanol) mixtures. Nitromethane made inert with methanol could be safely transported to the point of usage and then sensitized immediately prior to use by addition of ethylenediamine.

A study of the detonation propagation in liquid mixtures of nitromethane with azidoethanol revealed that high-velocity detonation of the mixtures of nitromethane containing less 70% azidoethanol propagated steadily in thick-walled steel tubes [410]. Addition of 20% azidoethanol to nitromethane decreased the failure diameter from 13 to 9 mm (in glass tubes).

The heat of detonation and the combustion products formed during detonation of nitromethane were compared to those obtained from detonation of HMX, TNT, and bis[2,2-dinitro-2-fluoro-ethyl]-formal (FEFO) [411, 412].

3.11.2 Measured Lead Block Indentation of Nitromethane

Nitromethane is remarkably insensitive to shock. When it does detonate, however, it was found to be a very powerful explosive, with a lead block value of 135 cm^3 [413].

3.11.3 Measured Detonation Velocity of Nitromethane

The detonation velocity of nitromethane is 6650 m/s [413]. When comparing information on the detonation velocity of nitromethane, it is important to know if the nitromethane was sensitized by adding a trace of amine. Also, some reports failed to provide information on the type of confinement in steel pipes or other container materials.

The detonation velocity of nitromethane has been measured for various charge radii and confining materials. The detonation velocity and critical diameter as a function of temperature was measured for detonation of nitromethane in glass tubes [414]. Unconfined nitromethane in a 44-mm diameter charge had a detonation velocity of 6280 m/s , but confined samples in a 40-mm O.D. steel pipe detonated with 6320 m/s [378]. A critical diameter of 27 mm for the detonation of unconfined nitromethane has been found. In a 30-mm O.D. aluminum tube with 2.5 mm wall thickness the detonation velocity was $6600 \pm 130 \text{ m/s}$ [93].

The mass velocity profile of detonating nitromethane was measured with an electromagnetic sensor that registered changes in electromotive force (e.m.f.) of a metal probe entrained in the detonation front [415]. It was concluded that detected e.m.f. was due to electrochemical processes in the vicinity of the electrode surface. The probe was made from 0.03 mm thick aluminum foil. The oscillograms showed that the leading edge of the hypervelocity wave was very steep.

Nitromethane, because it is one of the most studied liquid explosives, and is also inexpensive, was used mainly to check out an experimental procedure. A few experiments were conducted on its isomer, methyl nitrite [416]. Reaction times for shock initiation were measured for some liquid explosives using a high-speed smear camera and a modified gap-test. In all cases the reaction times decreased as the initiating shock pressure increased in the range 70 to 130 kbar, and as the pre-shock temperature was raised in the range from 278 to 313 K (5–40 °C). For constant shock pressure, the reaction time for liquid methyl nitrite was significantly less than the reaction time for nitromethane. This was consistent with thermal explosion theory, because the $\text{CH}_3\text{O}-\text{NO}$ bond strength is more than 83.7 kJ/mol (20 kcal/mol) weaker than the CH_3-NO_2 bond. Graphs were used to illustrate the effect of pre-shock sample temperature and purity of nitromethane on reaction time. The reaction time at 298 K was 0.6 s at a peak pressure of 88 kbar and 2 s at a peak pressure of 80 kbar.

The change of electrical signals arising on two metallic electrodes which are submerged in detonating nitromethane can be used to measure the detonation velocity of nitromethane [417, 418]. The electrodes were thin flat-parallel bands of magnesium, aluminum or zinc. It was concluded that the detected emf. was due to electrochemical

processes in the vicinity of the electrode surface. Electroconductivity of detonation products behind the detonation front is mainly ionic. The electrode of readily oxidizable metal sends its cations into detonation products and is therefore negatively charged and this change can be recorded.

Nitromethane did not behave according to the Campbell-Travis model for detonation in liquid explosives but showed a behavior of liquid explosives very similar to that of solid polycrystalline explosives [419]. There was no evidence for a so-called superdetonation, which would start behind and overtake the pressure shock wave.

Deuterating the methyl group in nitromethane affects the processes that occur in the detonating liquid material. A study of diameter-effect curves (i.e., inverse charge internal radius vs. steady detonation speed) for pure CH_3NO_2 and pure CD_3NO_2 revealed large differences in the infinite medium (i.e., plane wave) detonation speed and in the failure diameter of the two materials [420]. The observed large decrease in CD_3NO_2 infinite medium detonation speed, relative to the protonated material, was interpreted in terms of the theory of steady-state detonation. The increases in nitromethane's failure diameter and its steady one-dimensional chemical reaction zone length due to deuteration depend on the quantity of NM *aci*-ions present.

One group of experimenters measured a failure wave velocity of 4.75 mm/ μs for nitromethane [421], but Stanford Research Institute (SRI) measurements of 3.881 mm/ μs [422] were much closer to the 3.72 mm/ μs measured by Davis and reported by Enig and Petrone [423].

3.11.4 Critical Diameter of Nitromethane Detonations

The critical diameter of unconfined nitromethane detonations was 27 mm [378]. With moderate confinement the critical diameter dropped to below 12 mm. Propagation of detonation of unsensitized nitromethane in 12-mm diameter pipe was often incomplete and can be interrupted by orifices, right-angle bends or sudden expansion into a larger diameter pipe. This phenomenon is often used in the design of detonation traps. For nitromethane sensitized with 5% ethylene diamine, the minimum propagating thickness was 1.6 mm.

The "unconfined" failure diameter of nitromethane was found to be greater than 11.76 mm [423]. Other investigators measured failure diameters of 18 mm at 293 K (20 °C) and 15.7 mm at 303 K (30 °C) for nitromethane with weak (glass) confinement [414].

Studies of detonation failure diameters were made on four liquid nitroalkanes (nitromethane, 1,1-dinitroethane, 1,1-dinitropropane, and 2,2-dinitropropane) under extreme conditions of lead block confinement and weak shell confinement [424]. Shock-induced reaction times and failure wave velocities in decaying detonation waves were measured and used to calculate the failure diameters of these unconfined liquids. The values of the unconfined failure diameters were acceptable when the CJ pressures were accurately known and the experimental shock-induced reaction times and failure wave velocities were used in the calculations.

The critical detonation failure diameter of nitromethane detonations below which the detonation is either slowed down, switches to a low-velocity detonation mode or is quenched altogether depends on many variables, such as type and amount of sensitizer, type and amount of diluents, gas saturation, pressure and temperature [425, 426]. It also depends on the sequence and timing of multiple shocks (incident and reflected) [427].

A magnetodynamic method for determining the particle velocity was used for the measurement of the velocities of detonation products of low-order liquid explosives (nitromethane and isopropyl nitrate) [428]. The objective was to determine the approach to equilibrium in the reaction medium. By an assay using the characteristics of the media in the presence and the space-time diagram of the sensor, it was shown that the profile-characteristic speeds highlight three areas. Characterized by the first acceleration sensor in the explosive charge, the second related to the re-ignition mechanism of the detonation front near the sensor, the third due to relaxation effects of the detonation products.

Taking advantage of the phenomena of nitromethane electric polarization under shock, the relation between pressure and particle velocity and the influence of pressure conditions on induction delays of the explosive were measured [429]. The pressure was generated either by an incident shock wave or by a shock wave reflected within a medium prepressurized by a first shock wave. It was observed that nitromethane compressed at 11 GPa by means of two shock waves did not detonate (during the observation time of about 0.5 μ s), while in the case of a single shock wave of the same amplitude the induction delay was lower than 0.1 μ s. These results showed the important role of temperature, as opposed to that of pressure.

3.11.5 Theoretical Prediction of Detonation Properties of Nitromethane

When studying the effects of replacing one of its hydrogen atoms with bromine or all its hydrogen atoms with deuterium, it was found that the failure diameter of deuterionitromethane in glass was more than double that of normal nitromethane. Similarly, critical diameters and diameter effect curves for nitromethane, bromonitromethane, and deuterionitromethane confined in brass were measured and deuterionitromethane had a larger critical diameter in brass than either nitromethane or bromonitromethane [430].

3.11.6 Hot Spot Theory for Detonation of Nitromethane

Small particles can be added to nitromethane to obtain a well-characterized heterogeneous explosive for experimental studies of shock initiation due to **hot spots**. Computational simulations of hot-spot initiation require a model with a good set of chemical reaction rates and an EOS with good thermal properties. Detonation wave properties of a model were compared with experimental data, also for an underdriven or CJ detonation wave in pure nitromethane [431].

3.11.7 Low Velocity Detonation of Nitromethane

Instrumented detonation tests showed that nitromethane is able to undergo a low-velocity detonation (LVD) reaction if confined in a steel tube and subjected to a shock wave of appropriate strength [432]. It was concluded that the occurrence of LVD in nitromethane requires such conditions as to enable both cavitation of the liquid and sufficient time for explosive reaction. The latter condition means a rather strong confinement, because of the relatively slow reaction rate of nitromethane. The results may lead to an improved design of a card gap test for the investigation of the shock wave sensitivity of liquids.

It is well known that in liquid explosives, propagation is by HVD or LVD, depending on the level of the initiating shock pressure. Two physical models emphasizing either the role of cavitation by precursor waves or the role of a Mach disc have been proposed to describe the propagation of LVD in liquid explosives like nitromethane. The structure of LVD in nitromethane was investigated optically using high-speed photography [433, 434]. Stable LVD in clean nitromethane was not observed, although a transient LVD was found. The generation of cavitation bubbles and the formation of a Mach disc play an important role in the propagation of LVD in nitromethane.

It was proposed that the propagation mechanism of LVD in liquid explosives is not a self-reactive detonation, but rather a supported-reactive detonation from the cavitation field generated by precursor shock waves; however, the detailed structure of LVD in liquid explosives has not yet been fully clarified. High-speed photography was used to investigate the effects of the precursor shock waves on LVD propagating in nitromethane held in various container materials [435]. Stable LVD was not observed in all containers, although transient LVD was observed. The interaction of multiple precursor shock waves, multiple oblique shock waves, and the cavitation field make the structure of LVD very complicated.

Some liquid explosives have two different types of detonation behaviors: HVD or LVD. The detonation behavior (LVD or HVD) depends on the energy of the initiating shock pressure. Multiple shock waves propagating in non-detonating nitromethane were observed for shock pressures below the range required for LVD, while above the LVD threshold range, HVD prevails [436].

The detonation velocities of nitromethane are 6700 m/s in HVD and 2500 m/s in LVD mode. In liquid explosives, the highest pressure of LVD changes with the type of explosive and conditions and has destructive power equivalent to C-J HVD. In an instrumented card gap test with PMMA gap width from 0 to 200 mm, both LVD and HVD could be observed, depending on the gap width [437]. The detonation velocity was the same if the tests were conducted in copper or aluminum cylinders.

3.11.8 Sensitizers for Nitromethane as an Explosive

There are two methods for sensitization of nitromethane: chemical sensitization and mechanical sensitization. The mechanism of chemical sensitization is based on the

formation of *aci*-salts of nitromethane, which are much more sensitive than their parent compound. Sensitized nitromethane can be used as a liquid explosive (e.g., PLX). The sensitizer used most frequently is ethylene diamine. The mechanism of mechanical sensitization is due to inhomogeneities of materials with different sonic velocities, where shock waves may focus like light focuses optically in a biconvex lens and the elevated pressure initiates and propagates a detonation. Hollow glass spheres called microballoons have been added which collapse under the high pressure of a shock wave and propagate the detonation by adiabatic compression of the gas in the bubble.

3.11.8.1 Chemical Sensitization of Nitromethane

Amines are known to sensitize nitromethane to shock initiation. Data from a series of initiation experiments in which nitromethane was sensitized with diethylenetriamine (DETA, $\text{H}_2\text{NCH}_2\text{CH}_2\text{NHCH}_2\text{CH}_2\text{NH}_2$) showed some of the quantitative aspects of this amine sensitization [438, 439]. Testing different amines there was a correlation between the base strength $\text{p}K_{\text{a}}$ of the amine and the card gap width needed to prevent detonation. It was shown that the time delay to the appearance of a detonation front in nitromethane can be reduced from 18 μs to less than 1 μs with 0–5% DETA, and it was also seen that an overdriven detonation velocity appeared in solutions containing from 0.02% to 0.1% DETA. This overdriven detonation appeared to average as high as 6.76 mm/ μs over a run distance of about 10 cm at 0.05% DETA. The results of 1-in. cylinder tests were compared with calculated data. When testing different amines, there was a correlation between the base strength $\text{p}K_{\text{a}}$ of the amine and the card gap width.

The sensitivity of nitromethane and other nitroalkanes after addition of small amounts of amines was measured in a Naval Ordnance Laboratory (NOL) large-scale gap test [440].

Thermal decomposition experiments yielded substantially lower activation energies and an empirical sensitization factor for nitromethane mixtures that decreased as the nitromethane *aci*-anion concentration increased. Kinetic deuterium isotope analysis pointed to C–N bond scission as the rate-determining step in the thermal decomposition of nitromethane and nitromethane-amine mixtures [441, 442]. Laser ionization mass analyses of the solid nitro compound-amine mixtures indicated significant changes in the fragmentation patterns, with removal of the nitro group occurring in all cases as the first step in the breakdown of the mixtures, which was not the case for the pure materials. New absorption bands appeared in the UV/visible spectra of all the sensitized materials. These bands were ascribed to an intermolecular charge transfer from the nitrogen of an amine group to the anti-bonding orbital of the nitro group. It was shown that with small amounts of amines present, each amine molecule can form a complex with as many nitro compound molecules as there are amino groups on it. Combined with the assumption that the C–N bond breakage is the rate-determining step in the thermal decomposition of these materials, and the suggestion that

the dominant mechanism in their ignition/detonation is most likely thermal in origin, the sensitization mechanism can be explained.

Electronic and chemical changes in shock-compressed nitromethane and a mixture of nitromethane with ethylenediamine (0.1 mass-%) have been examined using time-resolved optical absorption spectroscopy under stepwise pressure loading to 14 GPa [443]. Despite the low amine concentrations, profound differences were observed in the absorption spectra of pure and sensitized nitromethane. The changes in the absorption spectrum of pure nitromethane involved a maximum absorption edge shift of 20 nm and were completely reversible. In contrast, the mixture showed an irreversible time-dependent shift in the absorption edge of up to 90 nm toward longer wavelengths. A substantial component of the shift took place after the sample had reached peak pressure. The time dependence and irreversibility of the absorption edge shift must be caused by a chemical change with the sensitization of nitromethane in the presence of amines.

The concentration of *aci*-anions in nitromethane/DETA mixtures can be measured by UV absorption and electrical conductivity [444]. The *aci*-anion is air-sensitive and its concentration will decrease if exposed to air.

The effect of varying the explosive sensitivity for a heterogeneous explosive charge formed of a packed bed of glass beads impregnated with liquid nitromethane sensitized with DETA was investigated [445]. The changes in the dependence of critical charge diameter on bead size was investigated at concentrations of 5, 10, and 15% DETA over a range of bead diameters from 66 μm to 2.4 mm. Additional measurements are also performed on the critical diameter of the homogeneous liquid explosive itself without any beads inserted.

The mechanism of sensitization of nitromethane by amines has been investigated by means of a computational density functional theory method [446]. Of the various possibilities examined, the most reasonable was that one involving the *aci* (nitronate) ion in an activated form which can interact with the amine eventually yielding another amine and the nitrite ion. The key features of this process are firstly an activation barrier less than the C—NO₂ dissociation of nitromethane, secondly a net release of energy and thirdly products that can sustain the reaction.

The critical diameter for detonation was measured for nitromethane sensitized with two different amines: DETA and triethylamine (TEA) [447]. The critical diameter in glass and polyvinylchloride tubes was found to decrease rapidly as the amount of sensitizer was increased, then increased past a critical amount of sensitizer. The critical diameter reached a minimum at an optimum concentration of sensitizer. It was also found that the critical diameter was lower with DETA than with TEA.

The effect of the addition of small amounts of DETA on the chemical reaction zone length of detonating liquid nitromethane was studied by making accurate measurements of the detonating materials' diameter-effect curves (i.e., detonation speed versus lateral charge size) as a function of the amount of chemical sensitizer added [448]. Detonation speed experiments were performed with additions of the organic base in

amounts between 0.00 and 0.25 mass-%. Reductions in the chemical reaction zone length of as much as 25% were produced by base addition. Most of the reduction in length was produced by very small amounts of base addition, i.e., ca. 0.05 mass-% of base or less (i.e., 1 molecule of the base per 3300 nitromethane molecules or less). Detonation speeds were measured for five compositions of nitromethane and base as a function of the charge internal diameter.

In addition to ethylene diamine, other amines used as sensitizers are DETA [449]. It was shown that small (0.0125–15%) additions of DETA lead to a qualitative change in the flow pattern in the reaction zone of detonating nitromethane. After the shock passed through, the mass flow rate continued to increase for about 10 ns, reached a maximum, and only then decreased. This is due to a sharp increase in the initial reaction rate.

Initiation of the shock-driven chemical reactions and detonation of nitromethane can be sensitized by the addition of weak bases; however, the chemical mechanism by which sensitization occurs remains somewhat unclear. The shock-driven chemical reaction in nitromethane and in nitromethane sensitized with DETA, using a sustained 300 ps shock was monitored with visible transient absorption spectra and measured interface particle and shock velocities of the nitromethane solutions using ultrafast dynamic ellipsometry [450]. Reaction occurred at an interface particle velocity of >2.4 km/s for neat nitromethane and >2.2 km/s for nitromethane with 5% DETA. The chemical reaction mechanisms for shocked nitromethane and nitromethane with DETA seems to be the same.

3.11.8.2 Mechanical Sensitization of Nitromethane

Another method to achieve mechanical sensitization of nitromethane is the addition of microballoons, hollow glass spheres. Another method of sensitization would be to create a nitromethane foam with many bubbles suspended in the (gelled) liquid.

Shock interactions at density discontinuities in nitromethane compressed by a planar shock wave can reduce the induction time for initiation of detonation [451]. The initiating efficacy of the discontinuity formed by a solid inclusion immersed in nitromethane strongly depends on the material used (silica) and the particle size.

Local hot spots behind inhomogeneities apparently produce an effective chemical reaction rate, which allows a stable steady-state flow at a much smaller charge size than is possible in homogeneous nitromethane confined in Pyrex tubes. Detonation-velocity measurements were carried out on cylindrical charges at a number of radii thus generating diameter-effect curves [452]. Silica particles with a known particle-size distribution were added to the nitromethane to produce a heterogeneous material and were held in suspension with a guar-gum gelling agent.

Mixtures of nitromethane and PMMA containing glass microballoons exhibited detonation properties more like solids than liquids because under shock conditions the heterogeneities produced hot spots which increased the energy release rate in

the nitromethane. Experiments were undertaken to determine **(1)** the relationship between steady-state detonation velocity and reciprocal charge size (the diameter effect curve) and **(2)** the critical diameter for mixtures of nitromethane-PMMA containing different concentrations up to 4.36% of glass microballoons with well-defined diameters in the range 37–50 μm [453]. Sets of experiments were performed in steel and plastic tubes to determine how the diameter effect curve and critical diameter of these mixtures.

The critical (i.e., failure) charge diameter and detonation velocity of liquid nitromethane sensitized with 15 mass-% of DETA in densely packed beds of solid spherical glass beads 66 μm –2.4 mm in diameter were systematically measured in unconfined charges over a wide range of bead sizes [454, 455]. It was found that there exists a critical bead size above which the critical diameter decreases with increasing bead size and below which it decreases with decreasing bead size. This indicated an abrupt change in the mechanism of propagation at the critical bead size.

Any inhomogeneity, solid or gaseous, will enhance LVD sensitivity. Nitromethane-silica mixtures containing size-selected silica beads at 6 mass-% were subjected to accurate shock input pressures [456]. The addition of beads was found to influence the shock sensitivity of the mixtures, with the smaller beads being more sensitizing than the larger beads, lowering the shock initiation threshold for the same run distance to detonation compared with neat nitromethane.

3.11.9 Explosive Performance of Nitromethane Mixtures

There are many nitromethane mixtures that have been evaluated as two-component explosives. Most of these are mixtures of nitromethane with liquid or solid oxidizers. These mixtures were formulated to be near stoichiometric for combustion to CO_2 . Mixtures can be homogeneous or heterogeneous (slurry or suspension). Other homogeneous mixtures with inert solvents were made to desensitize nitromethane and make it safe for transport.

Examples for stoichiometric liquid-liquid mixtures of nitromethane are those of nitromethane with nitric acid or tetranitromethane.

Liquid-solid explosive combinations are those of nitromethane with ammonium nitrate or ammonium perchlorate, also used commercially for demolition and excavation applications.

The critical diameter of nitromethane/acetone mixtures depends on the strength of the confining shell. The ratio of critical diameters of unconfined vs. confined 92 nitromethane/8 acetone mix is 20. The critical diameter of liquid explosives as a function of the wall thickness decreased sharply at comparatively thin wall thicknesses [457].

The width of the dark zone in streak-camera records defines the reaction zone region in detonating liquid explosives. A strongly boosted solution of 75/25

nitromethane/acetone showed a shortened reaction zone out to about 25 cm of free run [458]. The steady-state reaction time of diluted nitromethane was 0.4 μ s. The measured reaction time in undiluted nitromethane was 22 ns [459].

The effect of additions of HNO_3 , HClO_4 , CH_3COOH , methyl nitrate, triethylamine, diethylamine, acetone, methanol, CCl_4 or HCCl_3 on the detonation properties (detonation velocity and critical diameter) of nitromethane was studied in glass and steel tubes [460].

The detonation of mixtures of concentrated (94–100%) nitric acid with nitromethane was studied and the detonation failure diameter was measured in glass tubes [461]. For mixtures of nitric acid with nitromethane the minimum values of critical diameter were smaller than 1 mm and occurred at zero oxygen balance of the mixtures (stoichiometric ratio).

Mixtures of 2-nitropropane and nitric acid or mixtures of nitromethane with ammonium perchlorate (AP) are highly detonable and could be used as two-component explosives. The propagation and extinction of detonation in heterogeneous mixtures of spherulized AP with mean diameters of 9, 35, 90, 200, and 400 μ m were measured to study the effect of charge diameter, equivalence ratio of the mixture and the size of particles on the detonation velocity and critical diameter [462].

Sensitized nitromethane can be used as a field-filled homogeneous filling in shaped charges for the disposal of unexploded ordnance for both commercial and military applications [463].

Ultrafast optical interferometry was used to measure the Hugoniot pressure curve of an oxygen-balanced mixture of nitromethane and hydrogen peroxide (NM/HP) and to compare it with Hugoniot data for pure nitromethane and a 90% hydrogen peroxide/water mixture, as well as theoretical predictions [464, 465]. Unlike the Hugoniot of either HP or nitromethane, in which measured shock speeds deviate to values greater than the unreacted Hugoniot for piston speeds larger than the respective reaction thresholds, in the NM/HP mixture the shock speed deviations were lower than the unreacted Hugoniot. If this is a signature of chemical initiation, it would suggest that the process may not be kinetically limited.

3.11.10 Applications of Nitromethane

Nitromethane is widely used as a solvent. Solvent applications include polymers and coatings, as extraction or partition solvents, as reaction media or solvent in crystallization of organic compounds.

Large quantities of nitromethane are used as a paint, lacquer, and adhesive solvent. It is used as the solvent for cyanoacrylate polymers in “super glue”.

Nitromethane is sometimes used as a racing fuel additive in internal combustion engines in dragsters [466–468]. For that application it is usually mixed with methanol and sold under various brand names. One kilogram of nitromethane needs only 1.7 kg of air to burn. The same amount of gasoline needs 14.6 kg of air for optimum com-

bustion. That means that the cylinder of an engine can burn roughly 8.7 times more nitromethane on a stroke, generating 2.3 times more power than gasoline, but this is hard on the pistons and bearings, and the engines may not last very long. Some foolhardy racing car enthusiasts attempted to push the performance even further by adding hydrazine to the nitromethane, not realizing that the mixture is highly explosive. Nitromethane mixtures are used as the fuel in glow-plug model airplane engines (often with castor oil as the lubricant, giving that characteristic odor of model airplane engine exhaust). In model airplane engines and glow-plug fuel, the primary ingredient is generally methanol with some nitromethane mixed in (10–65%, but rarely over 30% since nitromethane is more expensive than methanol) and 10–20% lubricants (usually castor oil and/or synthetic oil). Nitromethane has been evaluated as the fuel for miniature combustion piston engines for use in unmanned aerial vehicles (UAV).

Nitromethane has been tested in many laboratories as a rocket propellant in static firings but has not (yet) found any practical applications (see *Encyclopedia of Monopropellants*). The detonation of nitromethane is of practical interest for more than one reason. Nitromethane can be used as a propellant in pulsed detonation engines and rotating detonation engines, which is another reason why detonation of nitromethane is discussed here from both a theoretical and experimental point of view.

Sensitized nitromethane can be used as a liquid explosive (PLX). Nitromethane in combination with ammonium nitrate has been used as a blasting agent which is more energetic but also more expensive than ammonium nitrate fuel oil (ANFO).

Nitromethane-based liquid explosives have been evaluated by the military for minefield clearance and tunnel destruction and excavation [469, 470]. Extensive safety tests on nitromethane were done to support such military applications. Such safety tests can benefit other applications of nitromethane. In the patent literature there are numerous patents on gelled nitromethane with addition of oxidizers like ammonium nitrate or metals with high heat of combustion like aluminum flakes. A preferred gelling agent for nitromethane is galactomannan cyanoethyl ether (US Pats. 3666577, 3755292, and 3806465).

Nitromethane has been evaluated as a liquid gun propellant. In order to reduce its sensitivity, nitromethane was diluted with methanol [471, 472].

Nitromethane is miscible with high proportions of aromatic hydrocarbons and only sparsely miscible with aliphatic hydrocarbons at low concentrations. It is therefore a suitable solvent for the separation of aromatics from aliphatics in petroleum distillates by solvent extraction techniques. Nitromethane may also be incorporated into diesel fuels with up to 2% by mass to help increase power and to reduce exhaust smoke and improve the cetane number.

4 Dinitromethane

Dinitromethane, $\text{H}_2\text{C}(\text{NO}_2)_2$, DNM, CAS RN [625-76-3] is a volatile liquid with a sharp, acrid odor. It is unstable at room temperature and decomposes with evolution of nitrogen dioxide. It can be kept for longer periods only at temperatures below 273 K (0 °C) or in solution in inert solvents like benzene or tetrachloromethane. Although it has a higher oxygen content than nitromethane, it is not useful as a rocket propellant. Some of its salts are more stable than the parent compound. Dinitromethane is formed as an undesirable byproduct during the production of 1,1-diamino-2,2-dinitroethene (DADNE, FOX-7).

Treatment of the potassium salt of dinitromethane with hydrogen fluoride in ether gave a fairly stable dinitromethane that could be distilled [473, 474].

4.1 Physical Properties of Dinitromethane

The boiling point of dinitromethane is 312–313 K (39–40 °C) at 26 Pa (2 mm Hg), the refractive index n_D^{20} is 1.4480 (but another source listed 1.4732) and the density at 293 K (20 °C) is 1.524 g/cm³.

4.1.1 Thermodynamic Properties of Dinitromethane

Dinitromethane is rarely mentioned in the literature. The heat of combustion is 574 ± 0.8 kJ/mol (137.2 ± 0.2 kcal/mol), from which an enthalpy of formation of -105 ± 0.8 kJ/mol (-25.2 ± 0.2 kcal/mol) can be derived for the liquid. The enthalpy of formation of gaseous dinitromethane was estimated at -59.4 kJ/mol (-14.2 kcal/mol) [173]. An experimental enthalpy of formation of the vapor, $\Delta H_{298} = -61.5$ kJ/mol = -14.7 kcal/mol taken from Knobel et al. was recommended by NIST 97. It is not known what type of correction was applied to those data.

4.1.2 Molecular Structure of Dinitromethane

The molecular structure of dinitromethane was modeled by computational chemistry using different computational methods and compared to the structures of other nitromethanes.

The molecular geometries of dinitromethane and trinitromethane were optimized and their harmonic force fields were calculated [475]. The force fields obtained made it possible to reliably interpret the vibrational spectra of dinitromethane, trinitromethane, and a number of isotopomers of trinitromethane. The hybrid density functional method used was shown to accurately predict the structural parameters and vibrational frequencies for polynitromethanes.

A quantum-chemical study of reactions leading to the formation of *aci*-dinitromethane and its decomposition with elimination of water employed an *ab*

initio RHF method with inclusion of electron correlation, a density functional theory approach and a semiempirical method [195]. For dinitromethane, the barrier to reaction was substantially lower than for nitromethane. The estimates of the heights of the energy barriers to formation found from DFT calculations (218.5 kJ/mol for *aci*-DNM) were suggested to be the most reliable.

4.2 Chemical Properties of Dinitromethane

Dinitromethane can exist in two tautomeric forms:

Similar to trinitromethane, dinitromethane is an acid and forms a variety of salts which are only a little more stable than the parent acid. Dinitromethane reacts with two molecules of formaldehyde to form the diol

which can be used to form thermally more stable esters.

Gaseous products of the thermal decomposition of dinitromethane and potassium dinitromethanide were investigated by simultaneous DTA/FTIR analyses under isothermal or non-isothermal DTA conditions [476]. Nitrous oxide and carbon dioxide were detected by FTIR.

4.2.1 Salts of Dinitromethane

Seven salts of dinitromethane with organic bases were prepared by two different methods: either by neutralization of dinitromethane solutions with the appropriate base or by metathesis reactions between dinitromethane sodium salt and a respective organic base salt [477]. Crystal structures of formamidinium dinitromethanide, acetamidinium dinitromethanide, and propionamidinium dinitromethanide and ^1H and ^{13}C chemical shifts of all compounds were determined by XRD and NMR and their thermal stabilities were determined by DSC. These salts are more stable than the parent acid and are potentially useful as propellant ingredients.

Single crystals of the potassium, rubidium, and cesium salts of dinitromethane were examined by XRD, and the structure of the dinitramidate anion was derived from the Weissenberg XRD diagrams [478]. The N—C—N bond angle is 121° . The space group of all three salts is $P\bar{1}$. The nitro groups of the anion are rotated about 10° out of the plane of the N—C—N bonds. The potassium salt is less stable than the rubidium salt.

Guanidinium, triazolium, and tetrazolium dinitromethanide salts are thermally stable and can be relatively insensitive to impact [479].

4.2.2 Salts of Dinitrosomethane

Dinitrosomethane is an acid like dinitromethane, it also forms salts with a wide range of metals and bases. The blue color indicates that they may contain free radicals. Alkali dinitrosomethanides $M[HC(NO)_2]$ [$M = Li, Na, K, Cs$ K(18-crown-6-polyether)] were prepared, fully characterized, and are stable at ambient temperature [480]; however, alkali dinitrosomethanides are heat-sensitive and shock-sensitive and are highly explosive. It is doubtful if they can ever be used as rocket propellants.

5 Trinitromethane

Trinitromethane, also known as nitroform, NF, $HC(NO_2)_3$, CAS RN [517-25-9] is an oxidizer. Trinitromethane by itself is not typically used as an oxidizer or monopropellant. It is a net oxidizer since its oxygen balance is +37.1%. The physical and safety properties of trinitromethane are summarized here while applications of its salts as monopropellants are discussed in *Encyclopedia of Monopropellants*, and applications of its salts as solid propellant oxidizers will be discussed in future volumes of this series of *Encyclopedia of Rocket Propellants*. Trinitromethane may be an intermediate in the preparation of trinitromethanide salts and therefore its physical, chemical, and safety properties must be known. Trinitromethane is useful for introducing the trinitromethyl group into other moieties.

5.1 Production of Trinitromethane

Tetranitromethane is easier to obtain than trinitromethane and is a starting material for trinitromethane. The synthesis of trinitromethane is the removal of one nitro group from tetranitromethane by a reducing agent. Trinitromethane and its alkali metal salts can be prepared from tetranitromethane by reaction with an alkali metal nitrite and some alkali metal hydroxide or hydrogen carbonate which later regenerates some of the nitrite [481]. The reaction mixture at 323 K with 50/50 methanol/water as a solvent turns from colorless to red to yellow and becomes homogeneous within 20 min.

The various steps of the production of trinitromethane from acetylene involve nitration of acetylene, isolation of trinitromethane and recovery of concentrated nitric acid and oxides of nitrogen. The economic aspects and the layout of a production plant capable of producing 60 tons per year operating one shift per day were optimized [482].

Although nitroform is usually used up quickly at the same place where it is produced, it can be transported as a stabilized aqueous solution with urea, a water-soluble carbamic acid alkyl ester or a mixture of urea and a water-soluble carbamic acid alkyl ester as stabilizing agent [483].

4,6-Dihydroxypyrimidine (DHP) is a useful intermediate for the synthesis of trinitromethane without unwanted byproducts. DHP was prepared via cyclocondensation of dimethyl malonate and formamide as raw materials. Nitroform could then be obtained via nitration hydrolysis reactions of DHP [484]. Nitration of 4,6-dihydroxypyrimidine in sulfuric acid gave nitroform as the sole product by the formation of an intermediate, 5,5-dinitro-4,6-dihydroxypyrimidine, that underwent hydrolysis in the nitrating acid to *gem*-dinitroacetyl formamidine. This compound was further nitrated in the same reaction mixture to trinitroacetylformamidine, which finally underwent hydrolytic cleavage to nitroform. The *gem*-dinitroacetyl ureas were also able to produce nitroform on nitration.

Optimization studies showed that for up to 80% yield, the optimal reaction conditions were the molar ratio of nitric acid to DHP = 5 : 1, the molar ratio of sulfuric acid to nitric acid = 3.5 : 1.0, a reaction temperature of 318 K (45 °C) and a reaction time of 2 h [485]. Subsequently, hydrazinium nitroformate (HNF) with a purity of 98.9% was synthesized from the nitroform that was made by this method.

Trinitromethane can be made by incomplete nitration of acetic anhydride. Complete nitration would lead to tetranitromethane.

Trinitromethane can be made by treating acetone with an excess of nitrating acid at 333–373 K (60–100 °C) [486]. Instead of acetone, one can start with isopropanol, which most likely becomes oxidized to acetone and undergoes subsequent nitration [487, 488]. The effect of the nitronium NO_2^+ ion on the preparation of nitroform from isopropanol was investigated by using white fuming nitric acid (WFNA) and $\text{H}_2\text{SO}_4/\text{HNO}_3$ as nitrating agents. The results indicated that WFNA showed a better efficiency for the studied reaction. Furthermore, the effect of specific factors, such as reaction temperature, reaction time and molar ratio of nitrating agent to isopropanol, on the yield of nitroform was investigated. Pure nitroform could be obtained under optimized condition with a yield of 51%.

Nitroform can be prepared from a series of α -methyl carbonyl compounds such as acetylacetone as substrates using WFNA as the nitrating system [489]. Operating parameters such as additives, reaction temperature and time were optimized. Optimized conditions gave a nitroform yield of 40.8%.

Nitroform can be prepared by reaction of isopropanol with WFNA and concentrated sulfuric acid in dichloroethane as the solvent [490]. The reaction mixture was allowed to cool down and poured into ice water. Steam distillation gave trinitromethane in 25% yield which was washed first with diluted alkali and then with water. The product was then dried over anhydrous sodium sulfate.

5.2 Physical Properties of Trinitromethane

Physical and safety properties of trinitromethane are described in [491]. The physical properties of trinitromethane are summarized in Table 35.

Table 35: Physical properties of trinitromethane.

Property	S.I. units	Other units	Source	References
Molecular mass	151.0353 g/mol	6.621 mol/kg	NIST	[91]
Melting point	295 K 292 K	22 °C 19 °C	72 °F	Lewis and Smyth 1939 [492]
	299.4 K	26.3 °C	Konkova and Matyushin	[493]
	287.4 K	14.3 °C	Anonymous NIOSH 1981	[84]
Boiling point at 23 mbar pressure	321 K	48 °C	118 °F	Meyer, Koehler and Homburg [96]
Boiling point at 22 mm Hg pressure	318–320 K	45–47 °C	Kaye-Fedoroff Vol. 8	[491]
Density at 293 K		1.479 g/cm ³	Anonymous NIOSH 1981	[84]
Density at 298 K		1.59 g/cm ³	Meyer, Koehler and Homburg	[96]
Density at 297.4 K		1.5967 g/cm ³	Kaye-Fedoroff Vol. 8	[491]
Refractive index $n_D^{24.3}$		1.44174	Kaye-Fedoroff Vol. 8	[491]
Enthalpy of formation ΔH_f°	–38.5 kJ/mol	–254.9 kJ/kg	–9.21 kcal/mol JANA F 1964	[494]

Trinitromethane is quite soluble in water: 16.7 g/100 mL water at 273 K = 0 °C and 193.8 g/100 mL water at 333 K (60 °C). It is only sparsely soluble in ethanol: 5.29 g/L ethanol.

5.2.1 Crystal Structure of Trinitromethane

Trinitromethane crystallizes in space group C_3 . Surprisingly, no intermolecular C—H $\cdots$ O hydrogen bond bridges are formed [495]. Recrystallization of $(O_2N)_3CH$ from dioxane forms a 2 : 1 adduct $(O_2N)_3CH\cdots O(CH_2CH_2)_2O\cdots HC(NO_2)_3$ with dioxane which exhibits the shortest C—H $\cdots$ O bonds with a C—O distance of only 2.94 Å [496].

5.2.2 Molecular Structure of Trinitromethane

Trinitromethane (nitroform) can exist in two tautomeric isomers: a nitro form (I) and an *aci*-form (II):

The colorless form (I) exists in solutions acidified with hydrochloric or sulfuric acid and also in anhydrous benzene, carbon disulfide, or ether. Aqueous and basic solutions are intensely yellow due to the presence of the form II.

Trinitromethane has a propeller-like arrangement of its nitro groups, the symmetry of which is possibly relating to its lower than predicted (although still high) acidity, its *aci*-tautomerization, and the absence of expected very short C—H...O intermolecular bridges in the crystal is unusual [497]. A combination of crystallographic and computed data was used to explain the anomalous acidity which can be attributed to intramolecular and/or intermolecular electrostatic interactions. Decomposition via C—NO₂ bond scission may occur before *aci*-tautomerization can take place.

The dipole moment of trinitromethane is 2.71 D in accordance with its unsymmetrical tetrahedral structure [492].

The molecular geometries of dinitromethane and trinitromethane were optimized and their harmonic force fields were calculated [475]. The force fields obtained made it possible to reliably interpret the vibrational spectra of trinitromethane and a number of isotopomers of trinitromethane. The hybrid density functional method used was shown to accurately predict the structural parameters and vibrational frequencies for polynitromethanes.

Equilibrium angles, barriers to internal rotation and electronic structure of trinitromethane and its halo derivatives were described in [498].

5.2.3 Optical Properties of Trinitromethane

5.2.3.1 Infrared Spectra of Trinitromethane

The vibrational spectrum of trinitromethane was interpreted in terms of the additive interatomic interaction model on the basis of experimental IR and Raman spectra of HC(NO₂)₃, DC(NO₂)₃, HC(¹⁵NO₂)₃ and normal coordinate analysis [499]. The frequency assignment results were used in discussing its structure. It was shown that the symmetry of trinitromethane is below C₃ in the liquid state.

5.2.4 Thermodynamic Properties of Trinitromethane

Up until 1998, data reported in the literature for the enthalpy of formation of trinitromethane were quite contradictory. Older sources reported an enthalpy of formation of -77.8 kJ/mol (-18.6 kcal/mol) or -25.9 kJ/mol (-6.2 kcal/mol) for solid

trinitromethane and -21.3 kJ/mol (-5.1 kcal/mol) or -9.2 kJ/mol (-2.2 kcal/mol) for molten trinitromethane. The *NIST Chemistry WebBook* lists three different enthalpies of formation for liquid trinitromethane ranging all the way from -77.95 to -68.0 ± 3.1 to -32.1 kJ/mol but does not judge which one is the most accurate. The JANAF ingredients database (Jan 1964) listed an enthalpy of formation of -38.5 kJ/mol (-9.21 kcal/mol) for liquid trinitromethane.

The heat of combustion of trinitromethane was first reported as -458 kJ/mol ($-109.58 \text{ kcal/mol} = 726 \text{ cal/g}$) based on a single calorimeter run [15].

For the heat of combustion of trinitromethane, Holcomb and Dorsey gave a value of 458.6 kJ/mol (109.6 kcal/mol) and Picatinny Arsenal reported 521 kJ/mol (124.5 kcal/mol). An interpolation from a graphic method gave 526 kJ/mol (125.75 kcal/mol) [180].

Later, the heats of combustion of solid and liquid trinitromethane were determined in a microcalorimeter as $792.2 \pm 3.2 \text{ cal/g}$ and $816.5 \pm 2.8 \text{ cal/g}$, respectively [500, 501]. From these numbers the enthalpy of formation of solid nitroform at standard conditions have been calculated as being $-48.12 \pm 2.1 \text{ kJ/mol}$ ($-11.5 \pm 0.5 \text{ kcal/mol}$) for the solid, and for the liquid phase $-33.05 \pm 1.67 \text{ kJ/mol}$ ($-7.9 \pm 0.4 \text{ kcal/mol}$). From the relationship of the pressures of the saturated vapor over solid and over liquid trinitromethane the heat of sublimation was calculated as being $46.0 \pm 0.4 \text{ kJ/mol}$ ($11.0 \pm 0.1 \text{ kcal/mol}$), and the heat of fusion as being $32.6 \pm 0.4 \text{ kJ/mol}$ ($7.8 \pm 0.1 \text{ kcal/mol}$). The energy of dissociation of the C-H bond in trinitromethane was determined to be $420 \pm 12 \text{ kJ/mol}$ ($100.5 \pm 3 \text{ kcal/mol}$).

Enthalpies of formation of trinitromethane and its salts, C-N bond energies in nitromethanes, nitro group substituent effects on atomization enthalpies and formation enthalpies of nitromethyl radicals were summarized and reviewed on the basis of literature data and new thermochemical measurements [502].

The kinetics of thermal decomposition of nitromethanes provided a set of energies of dissociation of C-NO₂ bonds based on enthalpies of formation from research and literature data [37, 38]. These values enabled one to determine the enthalpies of formation of nitromethyl free radicals and the energy of dissociation of C-H bonds and the energies of dissociation of -NO₂ groups from radicals of the three nitro derivatives of methane.

The standard enthalpies of formation at 298 K and heat capacities and entropies in the temperature range of 300–5000 K for trinitromethane and a range of other nitro compounds were computed by means of a density functional theory in quantum chemistry [41].

The heat of vaporization of trinitromethane was estimated at 54.8 kJ/mol but this contradicts a heat of sublimation of $46.0 \pm 0.42 \text{ kJ/mol}$ reported in the same source (NIST). The heat of sublimation should be higher than the heat of vaporization, the difference being the heat of fusion. A more probable heat of vaporization is 32.6 kJ/mol .

5.3 Chemical Properties of Trinitromethane

The most remarkable property of trinitromethane is that it is an acid. The acidity of nitromethanes increase in the order nitromethane, dinitromethane, trinitromethane. As such, it can form salts with a variety of bases and these salts have been tested as solid propellant ingredients. The salts of trinitromethane are sometimes called “trinitromethides” or “trinitromethanides”.

One of the most thoroughly investigated trinitromethide salts is the hydrazinium(1+) salt, hydrazinium nitroformate, also abbreviated as HNF. The properties of HNF are described in *Encyclopedia of Oxidizers*, chapter “Hydrazinium Salts”. Several solid propellant formulations have been prepared with HNF. HNF is not very soluble in water, but nevertheless its solutions have been evaluated as “green” monopropellants (*Encyclopedia of Monopropellants*). Other nitroformate salts of organic amines are described in the chapters of the parent amine from which they were derived.

The other remarkable property of trinitromethane for its use as a rocket propellant ingredient is its oxidizing power and the excess oxygen in the molecule. Trinitromethane has an oxygen balance of +37.1% and a nitrogen content of 27.83 mass-% N.

5.3.1 Reactions of Trinitromethane

Trinitromethane is an acid and forms salts with a variety of bases. The salt formed from reaction with hydrazine (hydrate), hydrazinium trinitroformate, has been tested as a monopropellant and in solid propellant formulations. Trinitromethane is highly reactive and can add to unsaturated compounds and other organic compounds.

Trinitromethane adds readily in a Michael type of addition to α,β -unsaturated compounds such as acrylic acid and its esters, hydroxymethyl vinyl ketone, or nitroethylene. This reaction is used in the synthesis of 2-nitro-3-acetoxy-1-propene by way of a unique reaction of 1,1-dinitroethane and nitroform [503]. 4,4,4-Trinitrobutyric acid was converted to 3,3,3-trinitropropyl isocyanate and 3,3,3-trinitropropyl amine hydrochloride. Trinitromethyl carbamates were prepared by the addition of 2,2,2-trinitroethanol to various isocyanates and the addition of different alcohols to 3,3,3-trinitropropyl isocyanate. Trinitromethyl amines were prepared by the Mannich condensation of 2,2,2-trinitroethanol with various primary amines and the reaction of 3,3,3-trinitropropyl amine with nitroalcohols. Trinitromethyl heterocyclic compounds and 2,2,2-trinitroethyl esters are energetic compounds potentially useful as rocket propellants. Trinitromethane adds to activated double bonds, such as of α,β -unsaturated carbonyl compounds and vinyl ethers. It forms a complex with dioxane containing two mols of trinitromethane to one of dioxane, with a m.p. of 317.1–317.6 K (44–44.5 °C) and b.p. at 1 kPa (8 mm Hg) of 334–335 K (61–62 °C). It forms complexes with benzene and methylbenzenes.

The reaction of trinitromethane with formaldehyde gives 2,2,2-trinitroethanol which can be used for the synthesis of other energetic compounds.

The esterification of trinitroethanol with acetic anhydride gives trinitroethyl acetate which is more stable than trinitromethane itself and can be used as a solvent for nitro-cellulose. 2,2,2-trinitroethanol is described in *Encyclopedia of Oxidizers*, chapter "Nitroaliphatic Compounds".

The nucleophilic Michael addition of nitroform to acrylamide creates 4,4,4-trinitrobutanamide in the first step that can be converted to trinitropropylamine and salts containing the trinitropropylammonium cation, $[(\text{NO}_2)_3\text{CCH}_2\text{CH}_2\text{NH}_3]^+\text{X}^-$ [504]. For $\text{X}^- = \text{ClO}_4^-$, $(\text{NO}_2)_2\text{N}^-$, IO_4^- , or amino-bistetrazolate, these salts are of interest as propellant ingredients [505].

The reaction of trinitromethane with urea and acetaldehyde forms *N,N'*-bis(1,1,1-trinitroprop-2-yl)urea which can be converted to 1,1,1-trinitroprop-2-yl carbamate and 1,1,1-trinitroprop-2-yl nitrocarbamate which can be used as energetic additives or explosives [506].

5.3.2 Thermal Stability of Trinitromethane

5.3.2.1 Thermal Decomposition of Trinitromethane

The decomposition of trinitromethane (nitroform, NF) is of practical interest because trinitromethane is an intermediate in the production of hydrazinium nitroformate (HNF) and is a product of thermal decomposition and an intermediate in the combustion of HNF. There are several publications on decomposition of HNF which closely relate to the decomposition of NF. Nitroform is thermally unstable and decomposes already at its melting point of 287.4 K (14.3 °C) and is therefore not useful as a rocket propellant by itself.

When studying the decomposition of vapors of trinitromethane, fluorodinitromethane, and chlorodinitromethane under static conditions, it was noted that a significant influence on the rate is exerted by reactions proceeding on the surface of the reaction vessel [507]. A consideration of this reaction permits a determination of the characteristics of homogeneous decomposition, which, in the case of trinitromethane and fluorodinitromethane, indicates a radical mechanism of decomposition. The theory that H and F atoms have the same effect on the energy of cleavage of the C—N bond in nitro compounds studied was confirmed. The gas phase thermal decomposition of trinitromethane below 443 K (170 °C) and at an initial pressure of trinitromethane above 2.6 Pa (20 mmHg) proceeds with self-acceleration and has a pronounced induction period. With the addition of NO and NO₂ the decomposition rate of trinitromethane increased considerably and the induction period completely disappeared. In view of this, the acceleration of the reaction was attributed to the catalytic effect of the decomposition products

NO and NO₂. The gas phase decomposition of trinitromethane yields products typical for a monomolecular radical decomposition of polynitro compounds. The gas phase decomposition of trinitromethane followed a first-order equation. In the range 453 K < *T* < 473 K (180 °C < *T* < 200 °C), the reaction can be characterized by the following kinetic parameters: $E_{\text{act}} = 172\text{--}184 \text{ kJ/mol}$ (41–43.9 kcal/mol) and $\log A = 15.32\text{--}16.69 \text{ s}^{-1}$.

A hybrid method of density functional theory was used to compute optimized geometries of trinitromethane and some intermediates of its decomposition [CH(NO₂)₂, CH(NO₂)₂ONO, CH(NO₂), and HC(O)NO] and to locate the transition states of the dissociation and isomerization reactions involving these species [508]. The heat of formation of nitroform and of the intermediates of its decomposition and the Gibbs energies of activation of the reactions examined were calculated using *ab initio* multi-level procedures. The high-pressure limits of the rate constants of these reactions in the temperature range 300–2000 K were calculated using transition state theory or its variational analogue.

5.3.3 Radiolysis of Trinitromethane

Trinitromethane is formed during the radiolysis of tetranitromethane when the trinitromethyl radical abstracts a hydrogen atom from a solvent. The radiolytic decomposition of trinitromethane in solution by ⁶⁰Co γ-radiation has been measured by the decrease in the optical density at 350 nm [509]. The initial yield of this decolorization in molecules/100 eV was shown as a function of the pH. In strongly alkaline solutions the decolorization proceeded with a yield of 2.8 molecules/100 eV. It increased with increasing hydrogen ion concentration up to the value of 8.2 at pH 0. This high radiation sensitivity of trinitromethane in acidic solutions may be responsible for the low yields of trinitromethane in radiolysis of acid solutions of tetranitromethane. In alkaline solutions the absorption maximum of the C(NO₂)₃[−] ion at 350 nm not only became less intense but also was shifted to longer wavelengths. This indicated the formation of dinitromethane.

5.3.4 Trinitromethane Salts

Trinitromethane is a strong acid and forms salts with a variety of inorganic and organic bases. The salts are thermally more stable than the parent acid itself. The salts are potentially useful as oxidizers for solid propellants or, if dissolved in a solvent, as monopropellants. The most thoroughly investigated salt of trinitromethane is hydrazinium(1+) trinitromethide, also called hydrazinium(1+) trinitromethanide or hydrazinium nitroformate. A separate chapter has been devoted to this compound in *Encyclopedia of Oxidizers*, chapter “Hydrazinium Salts”.

Single crystals of potassium, rubidium or cesium trinitromethanide are unstable at room temperature and decompose within a few hours. The crystal structures of the three salts were determined by XRD [510].

The enthalpies of formation of the ammonium salts of trinitromethane and 1,1-dinitropropane have been determined by calorimetric measurements in a combustion bomb [511].

A combined method for determination of the standard enthalpies of formation of trinitromethane and its salts used the enthalpies of dissolution of trinitromethane and its ammonium, hydrazinium, guanidinium and potassium salts in water [512]. The enthalpy of combustion of hydrazinium salt of nitroform was determined by combustion calorimetry, and its standard enthalpy of formation was calculated. The enthalpy of formation of trinitromethyl anion in infinitely diluted aqueous solution was -24.94 ± 0.79 kJ/mol. Standard enthalpies of formation of trinitromethane and its salts are given in Table 36.

Table 36: Thermochemical properties of trinitromethane and its salts.

Compound	Enthalpy of solution, kJ/mol	Enthalpy of formation, kJ/mol
$\text{HC}(\text{NO}_2)_3$	19.71 ± 0.08	-44.65 ± 1.13
$\text{NH}_4\text{C}(\text{NO}_2)_3$	39.87 ± 0.08	-197.90 ± 0.88
$\text{N}_2\text{H}_5\text{C}(\text{NO}_2)_3$ ^a	50.04 ± 0.08	-76.86 ± 1.13
$\text{CN}_3\text{H}_6\text{C}(\text{NO}_2)_3$	49.12 ± 0.04	-213.14 ± 1.18
$\text{KC}(\text{NO}_2)_3$	64.10 ± 0.08	-341.18 ± 0.80

Data source: [493]

^a Heat of combustion is 1031.23 kJ/mol

The solid-state structures of three nitroformate salts were determined using single crystal X-ray crystallography [513]. The trinitromethanide anion was found to be a non-planar moiety which adopts either the commonly observed C_{2v} conformation or distorted propeller conformation (D_3) in the case of the silver salts or a C_2 conformation in the case of the potassium salt. This latter C_2 conformation has been uniquely observed for potassium trinitromethanide. All structures exhibited cation-anion interactions that influence the structure of the anion. The ^{13}C and ^{14}N NMR spectra of the trinitromethanide anion showed broad singlets, which indicated the equivalence of the nitro groups in solution within the NMR time scale. The gaseous decomposition products of potassium trinitromethanide at 298 K (25 °C) were detected using IR and mass spectrometry.

Guanidinium trinitromethanide is a relatively stable salt with a melting point of 401 K (128 °C) for the anhydrous salt, but it is usually obtained as the hydrate which melts at 395–397 K (122–124 °C). The anhydrous salt has a density of 1.643 g/cm^3 and a detonation velocity of 8200 m/s. The drop weight impact sensitivity with a 2.5-kg weight 50% point is at 17 cm.

Methylammonium trinitromethanide is a yellow solid with an m.p. (with decomposition) of 399–401 K (126–128 °C). It has been patented as a rocket propellant and explosive ingredient [514]. The vacuum stability of a 0.5-g sample of methylammonium trinitromethanide during 48 h at 333 K was 1.02 mL gas.

Tetra-*n*-butylammonium trinitromethanide is well crystallized and its crystal structure was determined by XRD, supported by ^{13}C and ^{14}N NMR spectra [515]. The trinitromethanide anion was found to be a non-planar system. The sum of dihedral angles between the central (C–N₃) plane of the anion and the planes of the individual nitro groups varies from 60 to 100°. The C–N and N–O interatomic distances in the trinitromethanide anion can be correlated with the dihedral angles of the corresponding nitro groups.

Trinitromethane was combined with oximes of cyclopentanone, cyclohexanone, and diphenylcyclopropenone and with melamine and two 1,3-dialkyl-2,4-dialkylimino-1,3-diazetidines to give simple trinitromethanide salt adducts [516]. Tricyanomethane was added to diphenylcyclopropenone oxime to give hydroxylamino-2,3-diphenylcyclopropenylium tricyanomethanide.

5.3.5 Other Trinitromethane Derivatives

Comparing the gas phase thermal decomposition of $\text{RC}(\text{NO}_2)_3$ compounds, where $\text{R} = \text{CH}_3, \text{C}_2\text{H}_5, \text{C}_3\text{H}_7$, it was found that the reactions are unimolecular and are characterized by high pre-exponential factors [517]. The activation energy is determined by the strength of the C–N bond. The effect of substituents R and molecular structure on the Arrhenius parameters for the radical decomposition of nitro compounds can thus be quantified.

Tetranitromethane, iodotritinitromethane, and *gem*-trinitroethane decompose in the liquid state with the same rates as in the gaseous phase [518]. The mechanism of decomposition in both states is identical.

The composition of the decomposition products of tetranitromethane, 1,1,1-trinitroethane, chloro-nitroform, bromo-nitroform, and iodo-nitroform in the gas phase as determined by GC-MS confirmed a radical non-chain mechanism of the decomposition, the first step of which is cleavage of the C–N bond [519]. A detailed decomposition mechanism has been proposed, considering the reactions of nitroalkyl radicals in systems containing NO and NO₂.

The theoretical molecular structures of trinitromethane derivatives $\text{XC}(\text{NO}_2)_3$ with $\text{X} = \text{H}, \text{F}, \text{Cl}, \text{Br}, \text{NC}, \text{NF}_2$ or N_3 were studied using a density functional theory method [520]. Graphs showed the dependence of the C–X bond length on the nature of X. In the sequence H, F, Cl, Br, the C–X bond length increased from 1.1 to 1.9 Å but the C–N bond changed only moderately. A similar correlation exists with X-CH_3 compounds. Corresponding compounds with X = iodine could not be studied.

Spectroscopic parameters of trinitromethane derivatives $\text{RC}(\text{NO}_2)_3$ with $\text{R} = \text{F}, \text{Cl}, \text{Br}, \text{I}, \text{NC}, \text{NF}_2$ or N_3 were determined experimentally and compared to computational predictions [521]. The experimental IR and Raman spectra of all trinitromethane derivatives were very similar. The most intense IR bands were observed at 1600, 1300, and 800 cm^{-1} while the most intense Raman lines were observed at 1350, 850, and 375 cm^{-1} . Their positions varied only slightly going from one compound to another. The calculated frequencies and the potential energy distributions over vibrations were tabulated, with the most detailed results obtained for $\text{FC}(\text{NO}_2)_3$ and $\text{ClC}(\text{NO}_2)_3$.

The trinitromethyl or trinitroethyl functionality is an important tool for the design of energetic materials. Theoretical calculations are capable of predicting some material properties. The synthesis, characterization, energetic properties and structure properties of several new promising trinitroethyl compounds possessing energetic material properties were reported and compared to standard explosives currently used [522, 523]. Based on a review of trinitroethyl-containing compounds available in the literature, it was observed that high density can generally be obtained in a more targeted manner in energetic materials taking advantage of non-covalent bonding interactions.

Trinitromethyl chloride is a useful chemical for the introduction of the trinitromethyl group into other molecules and the synthesis of energetic materials. The $\text{C}-\text{Cl}$ bond in trinitromethyl chloride is much shorter than in methyl chloride.

An evaluation of the potential use of trinitromethyl ethers, with the linkage $(\text{O}_2\text{N})_3\text{C}-\text{O}-\text{CR}_3$, a class of compounds that might have promise as superior oxidizers to replace ammonium perchlorate, did not result in the hoped for compounds [524]. Trinitromethyl ethers, trinitromethyl triazoles and non-anitroisobutane lacked the necessary stability.

Ten theoretical salts based on the nitroformate anion and various nitrogen-rich cations were designed and their molecular structure geometries were optimized using a density functional computational method [525]. The oxygen balance, enthalpies of formation, densities, detonation velocities and detonation pressures of these salts were calculated.

5.3.6 Combustion of Trinitromethane Derivatives

Because trinitromethane itself is not used as a rocket propellant, no strand burning data of pure trinitromethane are in the literature, but the burning behavior of many trinitromethane derivatives that are potential rocket propellant ingredients or explosives was studied in detail.

Hydrogen bonding affects the heat of sublimation and thermal stability, as evidenced by universal force field calculations [526]. The explosive properties of bis(2,2,2-trinitroethyl) nitramine (BTNEN) are shown in Table 37 in comparison to those of other common explosives. It is unique among other explosives in that it has a positive oxygen balance of +16.7%.

Table 37: Properties of BTNEN in comparison to other explosives.

Name	ρ g/cm ³	ΔH_f kcal/mol	P_{Det} GPa	V_{Det} km/s	Energy density kJ/cm ³	h^a cm	Oxygen balance %
BTNEN	1.96	−175.9	39.080	9.157	8.861	5	+16.7

5.4 Safety Properties of Trinitromethane

Trinitromethane would ordinarily not be handled in large quantities in the pure state by itself. Most applications would prefer it to be used only in solution while it is used as an intermediate in the synthesis of other chemicals. The safety and explosive properties of trinitromethane were determined only in comparison to that of other nitromethanes, to study the effect of progressive replacement of hydrogen atoms on methane by nitro groups.

5.5 Toxicity of Trinitromethane

Although trinitromethane is rarely used as such, the toxicity of trinitromethane has been studied and compared to the toxicity of nitromethane and tetranitromethane. The oral LDLo of trinitromethane in mice was 150 mg/kg and the oral LD50 was 300 mg/kg [527]. The exposure of mice to inhalation of trinitromethane for 2h gave an LDLo of 0.7 mg/L (113 ppm), an LC50 of 0.8 mg/L (130 ppm) and an LD100 of 1.0 mg/L (162 ppm). Symptoms observed prior to death included irritation of mucous membranes of the eyes and respiratory tract, dyspnea, excitability, motor incoordination, convulsions, and narcosis. Threshold concentrations of 0.04–0.05 mg/L (8 ppm) were noted in cats and rats where changes in conditioned reflexes and neuromuscular activity were observed. In continuation of this study, subchronic exposure by daily inhalation of 0.12 mg/L (19 ppm) trinitromethane vapor for 2h over a period of

2 months altered excitability of the nervous system, increased reticulocytes in the blood, produced 6–9% methemoglobinemia, and resulted in death of 46% of the rats. Inhalation of 0.002–0.01 mg/L (0.3–1.6 ppm) trinitromethane vapor for 4 h/day for 7 months altered the threshold of nervous excitability. See also reference [528].

5.6 Other Applications of Trinitromethane

Of particular interest is the use of nitroform as a starting material for the preparation of bis(2-fluoro-2,2-dinitroethyl) formal (FEFO) and 1,3-bis(fluorodinitroethoxyl)-2,2-bis(difluoroamino) propane (SYEP). Both FEFO and SYEP are energetic plasticizers that were evaluated in formulating solid propellants (*Encyclopedia of Oxidizers*, chapter “Nitroaliphatic Compounds”). Low-cost processes for their production were sought. This, of course, necessitated starting their production with low-cost nitroform. For instance, fluorotrinitromethane can be prepared by direct fluorination of trinitromethane in aqueous solution with diluted elemental fluorine [529].

6 Tetranitromethane

Tetranitromethane, $C(NO_2)_4$, CAS [509-14-8], in the following often abbreviated as TNM, would be a good rocket propellant oxidizer if one could deal with its shock sensitivity and toxicity problems. The oxygen balance of TNM is +49%. It has also been tested as an explosive ingredient in mixture with various fuels. Its sensitivity to explosions and the high melting point have prevented the use of TNM as an oxidizer in its own right. It is now only of historical interest when compiling a list of chemicals that have been considered as rocket propellants at one time or another. TNM has a very high density (1.64 g/cm^3) which makes it attractive for storable liquid propellants in pressure-fed systems. The volume-specific useful oxygen content (1.07 kg/L) expressed in kg of useful oxygen per liter, is the highest of all storable oxidizers and approaches that of liquid oxygen (1.14 kg/L). Oxygen atoms are packed in the nitro groups more densely than in liquid oxygen.

A comprehensive summary of information on the methods of preparation, physical and chemical properties and toxicity of tetranitromethane, summarizing literature that appeared in print up to 1974 and including a list of 317 references is available in reference [530]. This includes information on the various reactions of tetranitromethane with unsaturated compounds that lead to other energetic chemicals. Additional properties of TNM are summarized in reference [531].

6.1 Production of Tetranitromethane

Tetranitromethane is formed as a by-product during nitration of aromatic hydrocarbons with concentrated acids at high temperatures, as a result of ring opening. During times of high demand of TNT, it may be difficult to get rid of the excess TNM.

6.1.1 Production of Tetranitromethane from Acetylene

The main method for production of TNM proceeds by reaction of acetylene with nitrating acid in the presence of mercury(II) nitrate as a catalyst [532]. An apparatus was designed capable of producing 10 kg TNM/day. Similar reactions can be performed with ethylene and nitrating acid [533]. Acetylene or ethylene is absorbed with great ease into white fuming nitric acid and the TNM separates from the mixture [534, 535].

During World War II the Germans manufactured tetranitromethane by this method on a semi-commercial scale, after they had developed and improved the industrial process. The reaction takes place in the presence of mercury(II) nitrate as a catalyst at temperatures ranging from 318 to 323 K (45–50 °C) (max. 333 K = 60 °C):

The overall reaction may be presented as:

The yield of TNM is reduced by an unwanted side-reaction

Both reagents are readily available in industrial quantities. Just how to react a gaseous fuel (acetylene in itself is already detonable) with a liquid oxidizer without causing an explosion, that is not an easy task. See also reference [536].

6.1.2 Production of Tetranitromethane from Acetic Anhydride

It was found earlier that tetranitromethane is formed when fuming nitric acid is reacted with acetic acid, but for the preparation of tetranitromethane on the laboratory scale the method using acetic anhydride instead of acetic acid is preferred [537–539].

Of the many methods for the preparation of TNM, the reaction between acetic anhydride and nitric acid seems the most promising [540]. The reaction is best carried out in all-glass equipment consisting of a flask, mechanical stirrer, dropping funnel,

thermometer, and reflux condenser. Commercial WFNA can be used with success, but the yield of TNM is higher if the nitric acid is first purified by vacuum distillation. No advantage is gained in purifying the acetic anhydride. The optimum temperature of reaction is 293–298 K (20–25 °C), and the yield is enhanced by the presence of chipped glass. The yields of a considerable number of experiments averaged 61–62%.

Another method consists of treating acetic anhydride with fuming nitric acid at room temperature or below. After a few days of standing the homogeneous solution is poured into water, causing the oily tetranitromethane to separate. The reaction equation for the production of TNM from acetic anhydride and nitric acid is:

This method was applied in the USA. on a larger scale by Nitroform Products Co., Inc., Newark, N.Y.; however, the plant was completely destroyed by an explosion that occurred in the manufacture of tetranitromethane. Until 1953, TNM for the US Navy's research and development needs was available from the Nitroform Products Company, East Orange, N.J. In February 1953, the Nitroform Company facility was destroyed by an accidental explosion which killed all of the key personnel. The only other commercial supplier at that time was Johnson and Scudder, Bloomfield, N.J., but they were not interested in supplying larger quantities. Therefore, the US Navy began making it themselves for their own needs. Several hundred pounds of TNM have been prepared by the reaction of 96–98% nitric acid with acetic anhydride on a semi-pilot scale which was capable of producing 160 lb/month [541]. This somewhat hazardous reaction requires care and many precautions to conduct safely on an enlarged scale. The yields averaged 50% based on nitric acid and 35% based on acetic anhydride. After mixing WFNA and Ac_2O in an agitated and cooled kettle, the mixture was transferred to another kettle for the 5-day aging cycle. The kettles used for the aging cycle were cooled by circulating tap water. The temperature during the aging cycle was controlled at 298 K (25 °C) by adjusting the water flow to remove the heat of reaction. The impact sensitivity of the reaction mixture was measured immediately after the addition of nitric acid 1 day later, 5 days later, and that of the crude product after drowning and separation. All of these materials appeared to be insensitive and gave no explosion on the drop weight sensitivity testing machine with a 2.5 kg weight dropping from a height of up to 320 cm.

The acetic anhydride method is more expensive than the acetylene method and can be used for smaller scale production. This is the method that was used at IG-Farben during WWII when the German rocket development center in Peenemünde began to develop interest in this oxidizer [542–544]. When the reaction mixture is poured into ice water, tetranitromethane separates out. An alternate method is the reaction of acetic anhydride with N_2O_5 instead of WFNA.

6.1.3 Other Methods for Production of Tetranitromethane

Tetranitromethane may also be prepared by introducing a slow stream of ketene into cooled 100% nitric acid [545]:

When the reaction mixture is poured into ice water, tetranitromethane separates out. Tetranitromethane can also be produced by nitration of trinitromethane. The reaction of silver nitrite with iodotrinitromethane yields tetranitromethane. Another method is the reaction of nitryl chloride with sodium trinitromethanide.

TNM is formed as an undesirable byproduct during the production of TNT by nitration of toluene, following opening of the ring. It is a constituent of the so-called red water which is the waste stream of TNT production that is difficult to dispose of in an environmentally acceptable manner. Therefore, it is desirable that formation of TNM during nitration is minimized for safety and health reasons. Indeed, there is evidence that a reduction in the meta-isomer content of lower nitrated toluenes (MNTs and DNTs) will be effective in reducing TNM formation. Over 80% of all the TNM formed in the production of TNT is derived from such meta-isomers. Isotope labeling has shown that most of the TNM is formed from carbon atoms that were part of the benzene ring where the methyl group was attached. TNM also forms as an unwanted byproduct during the production of dinitrotoluene which is an intermediate for the production of toluene diisocyanate, an important building block for polyurethane polymers.

TNM is an unwanted byproduct of many industrial nitration processes. There are numerous patents describing the removal of TNM contamination from TNT and other nitration products. An attempt was made to effectively remove TNM from the effluent gas stream from TNT manufacturing operations and convert it to nitroform [546]. The TNM was efficiently removed by passing the gas through a column scrubber containing an aqueous solution of sodium carbonate and stabilized hydrogen peroxide. The resulting sodium nitroformate solution is a marketable by-product. See also [9, 547, 548].

Spent nitrating acid that is coming out of nitrating reactors may contain TNM that may accumulate in other locations of the process if it is not removed before the acid is recycled or neutralized. The removal of TNM from spent nitrating acid can be done by sparging with air or solvent extraction, followed by destruction [549].

In the recovery of acids from the nitration of toluene to TNT, it is possible under certain conditions to obtain mixtures of nitroaromatic compounds, primarily mononitrotoluene and dinitrotoluene with nitrogen tetroxide and/or tetranitromethane. These mixtures have the potential of being highly sensitive liquid explosives. Studies showed that such odd mixtures are not exceptionally sensitive to mechanical impact and friction or thermal initiation but at oxygen balanced proportions, are extremely sensitive to induced shock and are capable of propagating explosive reactions at film thicknesses of less than 0.5 mm [550].

For kinetic studies of reactions involving TNM, it may be useful to have isotope-labeled TNM. ^{15}N labeled tetranitromethane, $\text{C}(^{15}\text{NO}_2)_4$, can be prepared from ^{15}N labeled anhydrous nitric acid and acetic anhydride [551].

6.2 Physical Properties of Tetranitromethane

Rocket propellant chemists already started measuring and collecting the physical properties of TNM in the early days of rocket development in Peenemünde in Germany during the 1940s. Subsequently, several summaries of the properties of TNM were published [552] and some of the data from these sources are summarized here.

Physical properties of tetranitromethane were summarized in [553–555]. Other data came from manufacturer's marketing literature, data sheets that are no longer available.

6.2.1 Freezing Point and Phase Diagrams of Tetranitromethane

Freezing point data for tetranitromethane are summarized in Table 38.

Table 38: Summary of literature freezing point data for tetranitromethane.

Freezing point temperature			Data source	References
K	°C	°F		
286.95	13.8	56.8	Nicholson 1949	[554]
286.9	13.75	56.75		
287.286	14.136	57.44	Taylor	[556]

Tetranitromethane undergoes a phase transition in the solid state at 174.95 K [557]. The cryoscopic constant of TNM is 14.3 °C mol solute/kg TNM [558].

6.2.2 Boiling Point of Tetranitromethane

One must not attempt to distil TNM at sea level pressure because this may result in explosions. The boiling point of TNM at 760 mm is 126 °C = 259 °F [559, 560]. TNM can be distilled safely by steam distillation.

6.2.3 Density of Tetranitromethane

Literature data for the density of tetranitromethane are summarized in Table 39.

Table 39: Density of tetranitromethane.

Temperature		Density	Data source	References
K	°C	g/cm ³		
288	15	1.649	Nicholson 1949	[554]
293	20	1.630	Nicholson 1949	[554]
285.3	12.2	1.638	Hummel 1962	[561]
288	15.0	1.65	Hummel 1962	[561]
298	25.0	1.64	Hummel 1962	[561]
298	25	1.62294	Lewis and Smyth 1939	[492]
298	25	1.65	Taylor 1955	[541]
286	13	1.650	Dobratz 1972	[562]

6.2.4 Vapor Pressure of Tetranitromethane

Literature data for the vapor pressure of tetranitromethane are summarized in Table 40. It is the high vapor pressure and the toxicity of TNM that makes safe handling of this chemical as a rocket propellant a very difficult task.

Table 40: Vapor pressure of tetranitromethane.

Temperature		Vapor pressure		Data source	References
K	°C	kPa	mm Hg		
273	0	0.25	1.9	Nicholson 1949	[554]
287	13.8	0.76	5.7	Nicholson 1949	[554]
293	20	1.12	8.4	Nicholson 1949	[554]
303	30	1.98	14.9	Nicholson 1949	[554]
313	40	3.43	25.8	Nicholson 1949	[554]
293	20	1.12	8.4	Hummel 1962	[561]
303	30	1.98	14.9	Hummel 1962	[561]
313	40	3.52	26.5	Hummel 1962	[561]
343	70	14.4	108	Hummel 1962	[561]
373	100	45.1	339	Hummel 1962	[561]
313	40	3.52	26.5	Edwards 1950, 1952	[563, 564]
323	50	5.75	43.3	Edwards 1950	[563]
333	60	9.04	68	Edwards 1950	[563]
343	70	14.4	108	Edwards 1950	[563]
353	80	21.8	164	Edwards 1950	[563]
363	90	31.8	239	Edwards 1950	[563]
373	100	45.1	339.6	Edwards 1950	[563]

The TNM vapor pressure data of Nicholson can be expressed by the equation

$$\log p = 8.63 - 2260/T$$

where p is the vapor pressure in mm Hg and T is the temperature in kelvin. The same data in the form of the Antoine equation for the temperature range from 273 to 313 K are represented by the equation:

$$\log_{10}(P) = 1.75688 - [498.772/(T - 158.538)]$$

where P is the vapor pressure in bar and T is the temperature in kelvin. The TNM vapor pressure data of Edwards can be expressed by the equation [564]:

$$\log p = 7.23 - 2130/T$$

where p is the vapor pressure in mm Hg and T is the temperature in kelvin. The same data in the form of the Antoine equation for the temperature range from 313 to 373 K are represented by the equation:

$$\log_{10}(P) = 4.54919 - [1582.071/(T - 49.74)]$$

where P is the vapor pressure in bar and T is the temperature in kelvin.

6.2.5 Viscosity of Tetranitromethane

The viscosity data for liquid TNM are somewhat divergent, one source reporting a viscosity of 1.76 cPs at 293 K (20 °C) [559] and another source showing a viscosity of 1.19 cPs at 288.2 K (15.1 °C) on a graph [565].

6.2.6 Surface Tension of Tetranitromethane

Literature data for the surface tension of tetranitromethane are summarized in Table 41.

Table 41: Surface tension of tetranitromethane.

Temperature		Surface tension	
K	°C	dyn/cm	N/m
293	20	30.47	0.0305
298	25	29.44	0.0294
303	30	28.98	0.0290
308	35	28.74	0.0287
323	50	26.45	0.0264

Data source: Gmelin Handbook of Inorganic and Organometallic Chemistry

Note: 10^5 dyn = 1 N; 1 dyn/cm = 10^{-5} N/cm = 10^{-3} N/m

6.2.7 Optical Properties of Tetranitromethane

6.2.7.1 Infrared Spectra of Tetranitromethane

The IR spectrum of tetranitromethane is of importance for quality control of the oxidizer to make sure it is free from contaminants. The IR spectrum of tetranitromethane is the key to the operation of monitoring instruments that monitor the air in human-occupied work spaces in propellant and explosive factories. The IR spectra of tetranitromethane were obtained at 298 K = 25 °C (vapor), 291 K = 18 °C (liquid), 233 K = -40 °C (solid I), 185 K = -88 °C (solid I), 169 K = -104 °C (solid II) and 147 K = -126 °C (solid II) [566], Figure 8. Cooling curve IR spectral investigations showed that a transition between two crystalline forms of tetranitromethane occurred at 173.3 K = -99.8 °C and its character suggested an order-disorder transformation. The spectra of the vapor were best interpreted by a molecule with $S_4-\bar{4}$ symmetry whereas reported Raman spectra indicated a $D_{2d}-\bar{4}2_m$ symmetry in the liquid. A total of 25 fundamental frequencies were assigned to fundamental vibrations and additional frequencies not interpreted as fundamentals were also tentatively assigned to other movements in the molecule.

Figure 8: IR spectra of tetranitromethane (republished and modified from [566], with permission of © 1953 American Institute of Physics; permission conveyed through Copyright Clearance Center Inc.) Legend: Top: vapor at 298 K in 5-cm cell, solid line: vapor in equilibrium with liquid, dashed line: low pressure <0.5 mm Hg; Center: liquid at 291 K, solid line: 0.15 mm cell, dashed line: <0.03 mm film; Bottom: solid at 233 K

6.2.7.2 UV Spectra of Tetranitromethane

The UV absorption of TNM has a $\lambda_{\max}$ at a wavelength of ca. 275 nm with $\log \varepsilon = 2.2$.

6.2.7.3 Index of Refraction of Tetranitromethane

Literature data for the index of refraction of TNM are summarized in Table 42.

Table 42: Index of refraction of tetranitromethane.

Temperature		Index of refraction	Source	References
K	°C	n_D		
290	16.9	1.4398	Hummel 1962	[561]
293	20	1.4384	Nicholson 1949	[554]
298	25	1.4358	Nicholson 1949	[554]
298	25	1.43822	Lewis and Smyth 1939	[492]
298	25	1.4351	Taylor 1955	[567, 568]

6.2.8 Electrical Properties of Tetranitromethane

The dielectric constant of TNM at 25 °C is 2.251. The specific electric conductance of TNM at 25 °C is $1.0 \times 10^{-8} \text{ Ohm}^{-1} \text{ cm}^{-1}$ (*Gmelin Handbook of Inorganic and Organometallic Chemistry*).

The dipole moment of tetranitromethane is <0.7 D which indicates that it has a symmetrical tetrahedral structure [492]. The dipole moment of the perfectly symmetrical tetranitromethane molecule should, of course, be zero, while that of trinitromethyl nitrite (a suspected contaminant or isomer) would depend on rotation around the single O—N bond of the nitrite group and would vary from 3.4 to 0 with variation in the angular position around this bond.

6.2.9 Thermodynamic Properties of Tetranitromethane

Thermodynamic properties of TNM are summarized in Table 43.

6.2.9.1 Heat Capacity of Tetranitromethane

Phase changes of TNM in the solid state can be identified by IR spectra and by abrupt changes in the heat capacity [557].

6.2.9.2 Heat of Formation of Tetranitromethane

The heat of combustion of TNM in an atmosphere of CO is -2130 kJ/mol (-508.7 kcal/mol), from which number the standard enthalpy of formation of liquid TNM was calculated as $+36.8 \text{ kJ/mol}$ ($+8.8 \text{ kcal/mol}$) [569].

The originally measured value of $\Delta H_f^{298}(\text{L})$ of $+37 \pm 2 \text{ kJ/mol}$ was later revised by Cox and Pilcher [179] based on different calibrations as $+41.2 \pm 4.2 \text{ kJ/mol}$ [571]. Other sources report an uncorrected heat of formation of $+38 \pm 2 \text{ kJ/mol}$ [572].

Table 43: Thermodynamic properties of tetranitromethane.

	SI units		Other units		Data source	References
	kJ/mol	kJ/kg	kcal/mol	cal/g		
Enthalpy of formation, ΔH_{298}^f liquid	+36.82	+187.8	+8.8	+44.89	Gardner and Grigger 1963	[569]
Enthalpy of formation, ΔH_{298}^f liquid	+38.5	+196.4	+9.2	+46.9	Meyer, Koehler and Homburg	[96]
Heat of fusion (ΔH)melt	9.422	48.06	2.252	11.49	Sarner 1966	[570]
Heat of evaporation (ΔH)evap	43.09	219.8	10.3	52.54	Nicholson 1949	[554]
Heat of decomposition ($\rightarrow \text{CO}_2 + 2\text{N}_2 + 3\text{O}_2$)	374.5	1910	89.5	456.6	Tschinkel 1956	[559]
Enthalpy of formation, ΔH_{298}^f liquid	54.4	+277	+13.0	+66	Dobratz 1972	[562]

NIST molecular mass: 196.0329 g/mol = 5.1012 mol/kg

6.2.9.3 Heat of Fusion of Tetranitromethane

The heat of fusion of TNM is 9.42 ± 0.25 kJ/mol (2.25 ± 0.06 kcal/mol) [541].

6.2.9.4 Heat of Evaporation of Tetranitromethane

From the vapor pressure data, the latent heat of evaporation was calculated as 43.1 kJ/mol (10.3 kcal/mol) [554]. Similar calculations resulted in a heat of evaporation of 40.6 kJ/mol (9.7 kcal/mol) [563]. The Edwards data were later revised to match different calibrations and shown as 43.1 ± 2.1 kJ/mol at 313 K. Other sources showed a heat of evaporation of 43.9 ± 0.4 kJ/mol [572]. The heat of sublimation of solid TNM is 47.4 kJ/mol between 255 and 286 K.

6.2.10 Molecular Structure of Tetranitromethane

Tetranitromethane has four equivalent nitro groups attached to the central carbon atom and the bonds are at tetrahedral angles, $109^\circ 28'$. The C—N bond length of 1.46 Å and the N—O bond length of 1.21 Å are similar to those in nitromethane [573, 574].

The IR spectra of gaseous TNM indicated an S_4 symmetry of the molecule, thus proving an earlier hypothesis about an unsymmetrical trinitromethyl nitrite isomer to be wrong [575].

Infrared and Raman spectra of tetranitromethane have been recorded in the liquid and vapor phases as well as in solutions of TNM in several different solvents [576]. The bands were assigned to $-\text{NO}_2$ asymmetrical stretching, $-\text{NO}_2$ symmetrical stretching, $-\text{CN}$ stretching, $-\text{NO}_2$ bending, wagging and rocking, $-\text{NCN}$ bending and $-\text{NO}_2$ torsions. The measured vibrational frequencies were compared to predictions from two different computational methods, a semiempirical method and an *ab initio* method. The agreement between experimental data and predicted data was better for the *ab ini-*

tio method. The computed vibrational frequencies fit the experiment within $\pm 2\text{cm}^{-1}$. See also Figure 8.

Computational chemistry methods were again applied to study the mechanism of thermolysis of TNM and identify possible reaction channels [577]. The first step in the thermal decomposition of TNM involves dissociation of a C—N bond. Computed values for the activation energy and pre-exponential factors satisfactorily agreed with experimental ones.

The structure and vibrational frequencies for tetranitromethane were calculated using three different methods [578]. The structural parameters obtained from density functional theory were compared to results obtained with more conventional methods and to experimentally determined values. It was found that molecular geometries were best calculated using Møller-Plesset second order perturbation theory (MP2), local and hybrid density functional methods. The non-local density functional methods produced unacceptably long values for the C—N bonds. Hybrid density functional theory produced the best agreement of vibrational frequencies.

The C—NO₂ bond dissociation energies and the heats of formation of nitromethane and polynitromethanes (dinitromethane, trinitromethane, and tetranitromethane) in the gas phase at 298 K were calculated theoretically using density functional theory and other methods in combination with different basis sets [46]. As the number of NO₂ groups on the same C atom was gradually increased, one functional performed better than the other functional. Predictions for the enthalpy of formation in the gas phase were accurate with deviations of <2 kcal/mol from experimental data for CH₂(NO₂)₂ and CH(NO₂)₃. For the C(NO₂)₄ molecule, a different basis set augmented with polarization functions and diffusion functions was required to yield a good result.

It was sometimes difficult to obtain a molecular structure for the highly symmetrical molecule of tetranitromethane that was consistent with results from diffraction experiments and spectroscopic analysis, but the structure has now been determined more accurately both in the gas phase and in the solid state [579]. For the gas phase, a new approach based on a four-dimensional dynamic model for describing the correlated torsional dynamics of the four C—NO₂ units was necessary to describe the experimental gas phase electron diffraction intensities. A model describing a highly disordered high-temperature crystalline phase was established, and the structure of an ordered low-temperature phase was determined by XRD.

6.3 Properties of Tetranitromethane Mixtures

6.3.1 Solubility of Tetranitromethane

Tetranitromethane is sparsely soluble in water, but soluble in alcohol and ether. The solubility of TNM in water is 0.85 g/L at room temperature. Solubility of TNM and trinitromethane must be known to prevent the accumulation of these unwanted contaminants in process streams of nitration facilities [548].

6.3.2 Freezing Point of Tetranitromethane Mixtures

A number of additives were evaluated to lower the freezing point of TNM to where it can be handled as a liquid propellant over a wider temperature range. It was difficult to find additives that will lower the freezing point without increasing the shock sensitivity of TNM.

The most thoroughly examined oxidizer mixture with TNM is the mixture with dinitrogen tetroxide which was already discussed in *Encyclopedia of Oxidizers*, chapter „Dinitrogen Tetroxide“ [580–582]. Here we discuss mixtures of TNM with other organic compounds, which were added mostly with the intention of lowering its freezing point; however, in many cases the shock sensitivity of the mixtures was prohibitively increased and none of the mixtures has found practical application. Table 44 gives the freezing points of tetranitromethane/nitromethane mixtures.

Table 44: Freezing points of tetranitromethane/nitromethane mixtures.

Mass-% CH_3NO_2	Mol fraction TNM	Freezing point		Freezing point depression, °C
		K	°C	
2.0	0.938	283.6	10.5	3.3
5.0	0.855	279.6	6.5	7.3
15.0	0.638	271.8	−1.3	15
25.0	0.438	264.6	−8.5	22
50.0	0.237	247	−26	40

Data source: [559]

In addition to binary mixtures, also ternary mixtures of 33–95 mol-% N_2O_4 , 5–41% TNM and 0–56.5% MeNO_2 are candidate liquid oxidizers [583]. An oxygen-rich ternary mixture containing 53 mol-% N_2O_4 , 25 mol-% $\text{C}(\text{NO}_2)_4$, and 22 mol-% CH_3NO_2 freezes at 233 K (−40 °C), while the most oxygen-rich ternary mixture freezing at 223 K (−50 °C) contained about 47 mol-% N_2O_4 , 19 mol-% $\text{C}(\text{NO}_2)_4$, and 34 mol-% CH_3NO_2 . A mixture of 20% TNM and 80% dinitrogen pentoxide freezes at 267 K (−7 °C) and has been proposed as a hypergolic oxidizer [584].

Mixtures of TNM with aliphatic difluoroamino compounds, such as bis(difluoroamino)ethane $\text{C}_2\text{H}_4(\text{NF}_2)_2$, tris(difluoroamino)propane $\text{C}_3\text{H}_5(\text{NF}_2)_3$, tetrakis(difluoroamino)tetrahydrofuran, tetrakis(difluoroamino) butane $\text{C}_4\text{H}_6(\text{NF}_2)_4$, pentakis(difluoroamino) pentane $\text{C}_5\text{H}_7(\text{NF}_2)_5$ have been patented as rocket propellant oxidizers [585]. The inventor failed to verify that the two liquids are miscible over the entire range of mixture ratios and will not segregate on cooling. Mixtures of TNM with various aromatic hydrocarbons and aromatic nitro compounds were tested as potential liquid explosives. The less energetic ones in this list might be suitable as monopropellants as long as they are not too sensitive to thermal and mechanical stimuli [586]. Melting points of several such mixtures are summarized in Table 45.

Table 45: Eutectic points in binary mixtures with tetranitromethane.

Mixture component A	Eutectic point at		
	Component A, mass-%	K	°C
Benzene	30	257.0	−16.1
Nitrobenzene	43	253.7	−19.4
<i>o</i> -Nitrotoluene	58.5	244.6	−28.5
<i>p</i> -Nitrotoluene	17.5	274.6	+1.5
α -Nitronaphthalene	10.0	282.6	+9.5
<i>m</i> -Dinitrobenzene	30	284.8	+11.65
Trinitrotoluene	30	285.5	+12.36

Data source: [586, 587].

6.3.3 Shock Sensitivity of Tetranitromethane Mixtures

Stoichiometric nitromethane/TNM mixtures are less shock sensitive than hydrocarbon/TNM mixtures. Several of the nitromethane/TNM mixtures have been patented [588–591]. These will be discussed again in *Encyclopedia of Monopropellants*. For mixtures of TNM with benzene, a two-component liquid explosive, see also [592].

Table 46: Density and oxygen balance of propellant mixtures with TNM.

Fuel component	Fuel, mass-%	TNM, mass-%	Oxygen balance λ for combustion leading to:		Density at 20 °C, g/cm ³
			CO	CO ₂	
Methanol	100	—	—	—	0.792
Methanol	48	52	0.770	0.572	1.085
Methanol	46	54	0.800	0.588	1.100
Methanol	37	63	1.000	0.742	1.175
Methanol	26	74	1.429	1.000	1.265
Ethylene glycol monomethyl ether	100	—	—	—	0.965
Ethylene glycol monomethyl ether	43	57	0.742	0.572	1.260
Ethylene glycol monomethyl ether	41.5	48.5	0.800	0.606	1.270
Ethylene glycol monomethyl ether	33	67	1.000	0.742	1.332
Ethylene glycol monomethyl ether	23	77	1.409	1.000	1.413
Nitromethane	100	—	0.800	0.572	1.136
Nitromethane	81.3	18.7	1.000	0.705	1.205
Nitromethane	55.5	44.5	1.450	1.000	1.316

Data source: [559]

Mixtures of TNM with methanol or ethylene glycol monomethyl ether were considered as monopropellants, see Table 46; however, insufficient data are available on their shock sensitivity and they may be too sensitive for practical applications. These mixtures may only be detonable at the stoichiometric mixture ratio but may be safe monopropellants at off-stoichiometric mixture ratios.

6.4 Chemical Properties of Tetranitromethane

6.4.1 Reactions of Tetranitromethane with Inorganic Compounds

TNM hydrolyzes slowly with water to form trinitromethane (nitroform):

Pure TNM is colorless, but hydrolysis in the presence of moisture will cause it to turn yellow. With potassium hydroxide it forms the potassium salt of nitroform:

Reaction of TNM with alkaline species leads to formation of trinitromethane. The preferred alkali for this reaction is potassium ethylate or potassium hydroxide. The rate constant of trinitromethane formation by solvolysis of tetranitromethane in various polar and non-polar solvents can be determined by measuring the absorbance of the nitroform anion $\text{C}(\text{NO}_2)_3^-$ as a function of reaction time [593]. Two mechanisms involving heterolytic C—N bond rupture in water and homolytic C—N bond cleavage in the less polar solvents were proposed to account for the solvolysis reactions.

6.4.2 Reactions of Tetranitromethane with Organic Compounds

Tetranitromethane reacts with organic compounds having double bonds to form intensely yellow colored adducts. This reaction is very sensitive and may be used for detecting traces of unsaturated olefins in saturated paraffin fractions.

Tetranitromethane can be used for nitration of enol silyl ethers and aromatic compounds. It is also employed in the controlled photo-oxidation of sulfides to sulfoxides.

The fact that one of the four nitro groups reacts preferentially was the cause for some speculation that TNM might exist in the form of an isomer trinitromethyl nitrite $(\text{O}_2\text{N})_3\text{C}(\text{ONO})$ but this hypothesis has been eliminated by proving that TNM is a symmetric molecule [575].

Addition of solid ferrocene to pure liquid TNM caused a violent, exothermic explosion accompanied by an intense flash [594].

In the reaction of two mols of styrene with one mol of TNM, the heterocyclic compound *N*- α -phenyl- β -nitroethoxy-3,3-dinitro-5-phenylisoxazolidine was formed [595].

The kinetics and products for the reaction of TNM with inorganic ions and primary, secondary and tertiary alcohols have been investigated [596]. It seems that re-

action of an RO^- ion with TNM starts the sequence of reactions to yield RONO_2 as product.

The electrolytic reduction of polynitroalkanes by electrolysis of tetranitromethane or 1,1,1-trinitroethane is a method for the electrochemical denitration of polynitroalkanes, and it was shown that this method can be used for preparative purposes employing cathodes made from various materials [597]. It was proposed to use the electrochemical denitration method for the separation of mixtures of polynitroalkanes, and also for the removal of accompanying impurities from polynitroalkanes.

Many reactions of TNM with unsaturated compounds and oxiranes lead to nitrosubstituted heterocyclic compounds, many of which are suitable as propellant ingredients [598].

6.4.3 Analysis of Tetranitromethane

Tetranitromethane has been analyzed colorimetrically by its reaction with benzidine. It can be analyzed volumetrically by titration of the iodine liberated when TNM reacts with iodide in aqueous solutions. The reaction with hydrazine liberates an accurate amount of nitrogen gas that can be captured in a gas burette and measured [599]. The reaction that takes place is:

The trinitromethanide anion formed has a strong absorption at 350 nm and can be determined spectrophotometrically [600]. In a 1-cm path length cell, TNM can thus be determined at concentrations down to 2×10^{-5} M in air or in solution.

6.4.3.1 Analysis of Tetranitromethane in the Air

Tetranitromethane is a by-product of the nitration of toluene, a process performed on a large industrial scale. The air in work spaces where TNM may be present should be monitored to make sure that the tolerable concentration of TNM is not exceeded. Air samples can be passed through an impinger filled with ethanol and the absorbed TNM is reacted with benzidine. The color reaction was performed by adding a measured amount of benzidine solution in ethanol (1 g/L) to the TNM solution in ethanol, the pH of which was brought to 6 by means of pyridine [601]. The absorption of the solution is then measured at 400 nm in a spectrophotometer and compared to a calibration curve. The dye formed is sensitive to light and not very stable.

The NIOSH recommended method for analysis of TNM in air is with impingers with ethyl acetate as the absorbent, followed by GC analysis [602].

6.4.4 Decomposition of Tetranitromethane

6.4.4.1 Slow Thermal Decomposition of Tetranitromethane

Tetranitromethane is indefinitely storable at 273 K (0 °C). Above 303 K (30 °C), which is a warm room temperature in a tropical climate, it will decompose slowly under evolution of nitrous fumes. Above 313 K (40 °C) in a sealed container there will be a noticeable increase of pressure due to gaseous decomposition products.

Pure TNM can be heated to 373 K (100 °C) without exploding. The exothermic decomposition starts normally at 523 K (250 °C) which is substantially above its boiling point of 399 K (126 °C). In the presence of contaminants the autodecomposition reaction

may start at lower temperatures.

The thermolysis of tetranitromethane has been studied experimentally and computationally by semiempirical methods starting with the stable molecules and ending with the final products NO, NO₂, CO and/or CO₂ [603]. In agreement with the experimental data, the rate-limiting step has been found to be the monomolecular activation of a C—N bond, which can proceed either towards dissociation or towards isomerization to nitrite. A detailed reaction mechanism was proposed and every transition state was identified. The activation energy and the pre-exponential factor in the rate constant have been computed and found to be in good agreement with experimental results.

Tetranitromethane vapor at a partial pressure of 1 mm Hg diluted with helium to atmospheric pressure was passed through a stirred-flow reactor and the rate of conversion as a function of dwell time was monitored by GC [604]. Mass spectrometric analysis of the decomposition products showed NO, NO₂, N₂O, and CO₂.

The rates of thermal decomposition of tetranitromethane, chlorotrinitromethane, bromotrinitromethane and 1,2-dichlorotetranitroethane were determined in selected solvents at various temperatures [605, 606]. The results of this study were used to derive a mechanism for the decomposition. The rate equation for decomposition of TNM is:

$$k = 10^{16.5} \exp[(-38400 \pm 1400)/RT]$$

and the products of the reaction are:

The gas phase decomposition of tetranitromethane, hexanitroethane, chlorotrinitromethane, bromotrinitromethane, iodotrinitromethane and dichlorodinitromethane has been studied over a temperature range from 373 to 433 K (100–160 °C) using a manometric method [607]. The reactions were found to be homogeneous and first order. The rates were independent of vapor pressures and of nitric oxide, nitrogen peroxide and iodine additions. The parameters of the Arrhenius equation

have been determined and a qualitative analysis of the decomposition products has been carried out. The results were interpreted in terms of a radical non-chain mechanism, the C—N bond scission being the first step.

6.4.4.2 Rapid Thermal Decomposition of Tetranitromethane

A solution of tetranitromethane in benzene in the liquid phase decomposed at high pressure at a rate significantly exceeding the rate of decomposition of pure tetranitromethane under the same conditions [608]. The addition of toluene or nitromethane to tetranitromethane did not influence the rate of its decomposition in gas mixtures. This observation can be explained by the formation of charge transfer complexes in a solution of tetranitromethane in benzene. The thermal decomposition of tetranitromethane vapor was measured in shock waves [609].

6.4.5 Photolysis of Tetranitromethane

Tetranitromethane in polar or non-polar solvents was electronically excited with 248 nm, 15 ns pulses from an excimer laser and the transient species formed were detected and characterized by nanosecond time-resolved absorption spectroscopy [610, 611]. In aerated or deaerated polar solvents the NO_2 radical and the nitroform anion $(\text{NO}_2)_3\text{C}^-$, with absorption maxima at 350 nm, were formed. In non-polar solvents, electronic excitation of TNM lead to the formation of the NO_2 radical and a transient species with absorption at 307 nm, which was attributed to the trinitromethyl radical, $(\text{NO}_2)_3\text{C}^\bullet$. Prolonged irradiation of TNM in non-polar solvents resulted in the formation of nitroform with an absorption maximum at 290 nm, which is generated by $(\text{NO}_2)_3\text{C}^\bullet$ via H abstraction from the solvent. See also reference [612].

The products of the photolysis of TNM were monitored in the 10^{-8} – 10^{-3} s range by recording the optical absorption and electrical conductivity of the solutions [613]. In polar solvents, the anion of nitroform, $\text{C}(\text{NO}_2)_3^-$, was formed during the 20 ns laser pulse. The yields of $\text{C}(\text{NO}_2)_3^-$ were highest in ethanol and lowest in aqueous solutions. In water, ionic dissociation of tetranitromethane was the main photolytic decomposition mode. In the alcohols and acetone a two-step mechanism was proposed involving C—N bond rupture to form the trinitromethyl radical, which subsequently picked up an electron from the solvent to form $\text{C}(\text{NO}_2)_3^-$ and an electron deficient solvent state.

The principal result for the decomposition of tetranitromethane during pulse photolysis using a UV laser is the formation of trinitromethane anions [614]. The quantum yield for the photodecomposition of tetranitromethane in methanol or in 96% aqueous ethanol is higher than in the vapor phase.

The photolysis of TNM has developed into a useful synthesis tool for nitration of organic compounds and the synthesis of trinitromethyl-substituted energetic compounds, as described in a series of publications that continued for up to 45 sequels, with a few examples quoted here [615–618]. Aromatic nitration by TNM was shown

to be photochemically initiated but mixtures of TNM with pyridine may explode accidentally [619].

The photofragmentation dynamics of TNM were explored by spin-unrestricted time-dependent excited-state molecular dynamic computations [620]. The leading order process was represented by the molecule undergoing cyclic excitation and de-excitation. During excitation cycles, kinetic energy was assumed to accumulate to overcome the dissociation barriers in the reactant and subsequent intermediates. The dissociation pathway included the ejection of NO_2 groups followed by the formation of NO and CO.

6.4.6 Radiolysis of Tetranitromethane

Because it is unlikely that tetranitromethane-based rocket propellants would be used in outer space where they are subjected to cosmic radiation, one would not worry about the lack of radiolytic stability of TNM. It was discovered that TNM acts as a free radical scavenger similar to NO in some radiolytic reactions where free radicals maintain a decomposition reaction [621]. One must be careful to avoid the formation of explosive mixtures during radiolysis experiments with TNM.

6.5 Strand Burning of Tetranitromethane and Tetranitromethane Mixtures

Encyclopedia of Monopropellants contains a comprehensive discussion of the strand burning of tetranitromethane and tetranitromethane mixtures, also with reference to accidental explosions of such mixtures.

6.6 Materials of Construction for Tetranitromethane

Glass, stainless steel, lead or aluminum are not attacked by dry TNM. Plain iron, copper, bronze, or zinc are not suitable for use in contact with TNM. PVC, polyisobutylene, butyl rubber or latex rubber are not suitable for use with TNM, which will either degrade their mechanical properties or permeate through the materials.

6.7 Explosive Safety Properties of Tetranitromethane

6.7.1 Shock Sensitivity of Tetranitromethane

Pure TNM is not shock sensitive to mechanical impact but the presence of organic contaminants can dramatically lower its shock sensitivity to a point where it has to be handled with the same precautions as a liquid explosive.

Pure TNM is a relatively non-explosive liquid. The impact sensitivity on the Explosives Research Laboratory (ERL) drop-weight impact machine with 2.50 kg weight was above 320 cm (for comparison: TNT = 160 cm) [541].

Tetranitromethane could not be made to explode under the maximum impact load of the apparatus used when tested for impact sensitivity in comparison to glycerin trinitrate, ethylene glycol dinitrate, and other energetic liquids [363].

6.7.1.1 Shock Sensitivity of Tetranitromethane Mixtures

Mixtures of TNM with hydrocarbons like toluene have been reported as being explosive and more sensitive to shock than nitroglycerine. Preliminary studies of the sensitivity of TNM when mixed with nitromethane or nitrobenzene showed that the impact sensitivities of these mixtures do not bear out the extreme sensitivity reported in the literature [622]. Mixtures of TNM and nitrobenzene were found to be much more sensitive than mixtures with nitromethanes. With both substances the maximum sensitivity occurred at the stoichiometric composition for explosion to CO₂, see Table 47.

Table 47: Drop weight impact sensitivity of tetranitromethane mixtures.

Diluent	Mass-% TNM	Impact sensitivity with 2.5-kg mass, cm
Nitromethane	44.6	109
Nitromethane	21.2	196
Nitromethane	65	180
Nitromethane	85	210
Nitrobenzene	42.6	264
Nitrobenzene	61.7	44
Nitrobenzene	76.3	22
Nitrobenzene	82.8	47
For comparison:		
Nitroglycerine		4–5
RDX		22
TNT		160
Pure TNM		>320

Data source: [541]

In 1920 at the University of Münster in Germany during a chemistry class lecture a massive iron gas burner containing a residue of 10 g of a TNM/toluene mixture suddenly exploded. The detonation splintered the container, and of the 300 students in the area 10 were killed and 20 were injured (see additional information on this accident later).

The card gap sensitivity of TNM/benzene, TNM/methyl glycol, and TNM/nitromethane mixtures was determined over a wide range of mixture ratios [623]. The

Figure 9: Card gap sensitivity of tetranitromethane mixtures (reproduced and modified from [623], with permission from © 1958 American Chemical Society; permission conveyed through RightsLink.)

higher the number of cards to prevent explosion, the more sensitive the explosive mixture is. The results are illustrated in Figure 9. While TNM/methyl glycol and TNM/nitromethane mixtures showed a maximum of sensitivity within the capability of the test method (<300 cards), a wide range of TNM/benzene mixtures required more than 300 cards to obtain a no go result and the maximum of the sensitivity could not be determined.

6.7.2 Adiabatic Compression Sensitivity of Tetranitromethane

Ethyl nitrate and *n*-propyl nitrate were used to calibrate an adiabatic compression U-tube test apparatus in preparation for additional tests with tetranitromethane and difluoroamino compounds [624]. The average 50% probability pressure ratio derived from a probit plot using the up-and-down method for ethyl nitrate was 7.81 ± 0.71 . Five tests were conducted to evaluate the sensitivity of TNM at ambient temperature ($\sim 294\text{ K} = \sim 70^\circ\text{F}$). In all cases, dry air in the gas bubble and the maximum driving pressure of 12.4 MPa (1800 psi) were used. The gas bubble was partially evacuated during some tests to obtain higher driving pressure ratios. No positive reactions were obtained up to the maximum driving pressure ratio of 256.

6.8 Detonation Properties of Tetranitromethane

The detonation velocity of pure TNM is $6360 \text{ m/s} = 20900 \text{ ft/s}$ at $\rho = 1.637 \text{ g/cm}^3$. Other sources give a detonation velocity of 6400 m/s for pure TNM with a density of 1.64 g/cm^3 [562].

The detonation front structure and parameters in solid and liquid tetranitromethane were investigated using a Doppler Fabry-Perot velocimeter, recording the particle velocity of explosion products braking on the high explosive/window interface [625]. A smooth front of the detonation wave and concave negative-going particle velocity profile were observed for liquid TNM. The experimental records indicated that because of solid TNM heterogeneity, turbulization occurred behind the detonation wave front, which became evident in the form of velocity fluctuations in the $U(t)$ profile.

6.9 Explosive Performance of Tetranitromethane

In the Trauzl lead block test, pure TNM gave an indentation that was 21.4% of that of TNT.

6.9.1 Detonation of Tetranitromethane Mixtures

The explosive properties of mixtures of tetranitromethane and nitrobenzene have been known for a very long time but little is known about their actual use in the field. Mixtures of tetranitromethane with fuels are more suitable as explosives than as rocket propellants. The adiabatic explosion temperature of TNM is 2948 K (2675°C), the detonation velocity in 21-mm diameter steel pipes is 6400 m/s [626].

Mixtures of tetranitromethane with pyridine may explode accidentally [619].

The detonation velocities and the Trauzl lead block indentations of the same TNM/organic compound mixtures studied in the first part of this two-part publication (see mixtures listed in Table 45) were measured in 9.5 and 22-mm diameter charges [627]. The highest detonation velocities were observed with mixtures of 78.7% TNM and 21.3% *p*-nitrotoluene (8170 m/s) or 80.3% TNM and 19.7% α -nitronaphthalene (8160 m/s). The highest lead block expansion (650 cm^3) was achieved with a mixture of 65.95% TNM and 34.05% *m*-dinitrobenzene.

Lead block indentations of TNM mixtures are compared to those obtained with glycerin trinitrate and TNT in Table 48.

Mixtures of TNM with organic fuels are shock sensitive and detonable. A mixture of TNM and toluene detonated in an auditorium during chemistry classes taught at the University of Münster in Germany, resulting in several fatalities [628–630]. This explosion occurred in the overcrowded lecture hall on 27 May 1920, when in a lecture on combustion with combined oxygen a cutting torch device employed in the first year of

Table 48: Lead block indentations of TNM and TNM mixtures

Detonator size	Pure TNM	70 mass-% TNM + 30 mass-% N ₂ O ₄	87 mass-% TNM + 13 mass-% benzene (stoichiometric)	For comparison	
				TNT	Glycerin trinitrate

5	71	37	445	332	397

Trauzl block, 10 g sample, widening of a 20 cm³ bore measured in cm³ as a measure for explosive power, from [559]

World War I for cutting-burning through barbed wire entanglements of front line barricades and in which toluene was the fuel and C(NO₂)₄ the supporter of combustion, was demonstrated. This device consisted of a piece of steel tube 20 cm long by 2.8 cm in diameter closed at one end. When filled with 15 g of cotton or cellulose wadding the stuffing will absorb 75 mL of a mixture of 7.5 mL of toluene and 67.5 mL of C(NO₂)₄ without any of the liquid running off. This material burns quietly and slowly at the regular rate of about 4 cm in 3/4 min., giving a very hot flame containing an excess of oxygen. The time for complete burning of the charge in the apparatus was about 3 1/2 min. On the day of the accident the charge had behaved as expected for about 3 min., the demonstration in wire cutting, etc., was finished and the quiet burning out of the remainder was awaited as usual when a violent explosion occurred, rending the steel burner tube into many small pieces, killing 5 students outright and wounding 5 others fatally. In all, 30 out of the 300 present were struck. The damage to the apparatus and building was extensive. Investigation showed that the lecture journal from which the assistant secured his instructions had recently been rewritten and that the unit of gram had been inadvertently entered instead of mL in recording the quantities of the components to be used in this mixture. Hence in this fatal experiment the mixture consisted of 7.5 g of toluene and 67.5 g of C(NO₂)₄. As the specific gravity of toluene is 0.8 and that of C(NO₂)₄ is 1.65, the weight of toluene in this mixture was nearly double that intended.

The shock sensitivity of TNM/toluene mixtures was measured in a gap test that used water instead of plastic cards to fill the gap between the donor and acceptor charge [631].

The minimum gas pressure of an oxygen/methane mix in the donor section to initiate detonation of a TNM/benzene mixture (1.5 TNM/1 benzene by volume) in a 30-mm O.D. Plexiglas tube was 2 atm, where two out of three tests resulted in a detonation [632]. Using an incrementally higher gas pressure of the oxygen/methane mix in the

donor section, the detonation time lag in the liquid explosive decreased from 350 to 10 μ s.

Rapidly cooled mixtures of TNM and benzene will contain small crystals (5–10 μ m) of TNM suspended in benzene. At even lower temperatures, both oxidizer and fuel will freeze. The detonation velocity of TNM/benzene mixtures was measured at different temperatures [633]. The detonation velocity of the liquid homogeneous 70 TNM/30 benzene solution at room temperature was 7680 m/s, but the two-phase, inhomogeneous, rapidly cooled mixture detonated at varying speeds between 3340 and 6500 m/s, depending on the temperature.

The detonation of tetranitromethane/ethyl iodide mixtures with volume ratios ranging from 27/73 to 30/70 was tested in flat channels of constant depth but varying diameters to determine critical diameters and propagation through narrow passages or sharp bends where the detonation wave would be attenuated or quenched [634].

The effects of hexane, propylene oxide, chloroform, and tetrachloromethane on the detonation properties of TNM were studied experimentally in 25-mm charges [635]. The densities of TNM mixtures with these additives were measured at 283–303 K. The density as a function of the TNM concentration and temperature was linear for mixtures all except those with CCl_4 . The detonation velocities for mixtures containing hexane or propylene oxide had a maximum at the stoichiometric composition. A TNM/hexane mixture containing a mol fraction of 0.715 TNM had a density of 1.3473 g/cm³ and a detonation velocity of 7207 m/s. The critical diameters below which detonation would no longer propagate were determined for all four mixtures [636]. Measured detonation velocity data were compared with those calculated by using a Becker-Kistiakowsky-Wilson EOS.

A laser interferometer was used to measure mass velocity profiles in steady-state detonation waves in tetranitromethane and its mixtures with methanol [637, 638]. In the experiments with tetranitromethane, the chemical spike pressure was found to be 1.7 times higher than the CJ pressure. A 50% increase in methanol concentration led to instability of the detonation front manifested in oscillations in the mass velocity profiles. The detonation velocity of TNM/MeOH mixtures increased from 5400 m/s at 0% MeOH to a maximum of 7100 m/s at 20% MeOH which corresponds to a small positive oxygen balance (equal to + 9%), and then dropped to a low of 5800 m/s at 60% MeOH. The detonation became unsteady when the MeOH content was increased beyond 40%. Stoichiometric zero oxygen balance corresponds to a TNM/methanol ratio of 75.4/24.6.

The effect of dilution of tetranitromethane by methanol on the process of detonation was studied over a wide range of diluent concentrations [639]. Experiments on the ignition of mixtures in steel tubes of various diameter were performed to obtain data on the critical (limiting) diameters. The results were compared with those from previous studies of mixtures of nitromethane with methanol and nitrobenzene. There may be chemical interactions of tetranitromethane as an active oxidizer with methanol as a fuel component in the reaction zone. The detonation velocity depen-

dence on methanol concentration goes through maximum near stoichiometric compositions calculated for total oxidation of fuel elements [640].

6.10 Toxic Properties of Tetranitromethane

The toxicity of TNM has been known for 100 years [641]. Tetranitromethane is very poisonous and has been the cause of several accidental fatal poisonings, mostly in connection with the production and storage of trinitrotoluene where it is formed as a volatile by-product [642–644]. Some toxicity publications erroneously still report that TNM is used as a rocket propellant, when actually it is no longer used as such. A long time ago it has been evaluated as a rocket propellant but that is now history.

The acute toxicity of TNM is first and quickly noticeable in the form of irritation of the mucous membranes in the eyes, nose and respiratory tract. The next symptoms are increased salivation, inflammation of the nose and upper respiratory passages, accompanied by headache or nausea. Repeated exposure leads to chronic poisoning evidenced by headaches, continued fatigue, sleeplessness, slowing of the heartbeat (bradycardia), methemoglobinemia, carboxyhemoglobin formation and respiratory distress, accompanied by anomalies of the central nervous system and irregular heartbeat. Skin irritations were rarely observed.

Inhalation of tetranitromethane causes nasal passage irritation and pulmonary carcinogenesis in rodents [645]. A very detailed summary of the toxicity of TNM has been published as part of an IARC monograph [646]. The animal test acute toxicity levels are summarized in Tables 49 and 50.

Summaries of toxicity information for trinitromethane and tetranitromethane were compiled in a government report [649]. Oral and inhalation toxicities and the degree of histological damage increase with increasing molecular weight of the compounds. The following Table 51 gives TNM acute toxicity data obtained from animal exposure tests.

Table 49: Acute toxicity animal tests with tetranitromethane.

Animal	Mode of administration	LD50, mg/kg	LC50, ppm
Rat	p.o.	130	
Rat	Inhalation		18
Rat	i.v.	12.6	
Mouse	p.o.	375	
Mouse	Inhalation		54
Mouse	i.p.	53	
Mouse	i.v.	63.1	
Cat	Inhalation		100

Data source: [84]

Table 50: Toxicity of tetranitromethane in rodent animal tests.

Species/Sex	Route	Measure	Value
Rat, Sprague-Dawley male	Oral	LD50	130 mg/kg (83–205)
Mice, CF-1 male	Oral	LD50	375 mg/kg (262–511)
Rat, Sprague-Dawley male	Intravenous	LD50	12.6 mg/kg (10.0–15.9)
Mice, CF-1 male	Intravenous	LD50	63.1 mg/kg (45.0–88.7)
Rat, Sprague-Dawley male	Inhalation	LC50	17.5 ppm (16.4–18.7) 0.14 mg/L
Mice, CF-1 male	Inhalation	LC50	54.4 ppm (47.0–61.7) 0.44 mg/L

Data source: [647, 648]

Route	Species	Dose	Response
Oral	Rats, male	130 mg/kg	LD50
Oral	Mice	380 mg/kg	LD50
Inhalation	Rats, male	18 ppm for 4 h	LC50
Inhalation	Mice	54 ppm/for 1 h	LC50

Data source: [650]

Chronic exposure tests to low levels of TNM extended over 2 years showed significantly increased frequency of tumors in bronchiogenic carcinoma. Based on these data, TNM has been categorized as a group 2B carcinogen by the IARC Carcinogen List criteria. It may also be a mutagen and cause DNA damage.

The mechanisms underlying carcinogenesis induced by TNM have not yet been clarified. It was previously revealed that nitrosotyrosine and nitrosotyrosine-containing peptides caused Cu(II)-dependent DNA damage in the presence of P450 reductase, which is considered to yield nitroreduction. Since TNM is a reagent for nitration of tyrosine in proteins and peptides, it was hypothesized that TNM-treated tyrosine and tyrosine-containing peptides induce DNA damage by the modification of tyrosine. DNA damage induced by TNM-treated amino acids or peptides using 32P-5 end-labeled DNA fragments obtained from the human p53 tumor suppressor gene and the c-Ha-ras-1 protooncogene was detected [651]. Time-of-flight mass spectrometry confirmed that reactions between Lys-Tyr-Lys and TNM yielded not only Lys-nitroTyr-Lys but also Lys-nitrosoTyr-Lys. Therefore, it was speculated that the nitrosotyrosine residue can induce oxidative DNA damage in the presence of Cu(II) and NADH.

For government regulatory agency activities, in particular those affecting drinking water quality in the vicinity of explosives manufacturing plants, there was a deficiency of data on TNM based on which safe contaminant levels of TNM in drinking water could be established and Drinking Water Health Advisories could be issued [652]. This report contains a good summary of toxicity data on TNM as they were known at that time.

Inhalation of tetranitromethane by rats (20 animals in each group) at 3 levels of concentration, 1230, 300, and 33 ppm, caused death in 50% of the animals in 36.3 min, 60 min, and 5.8 h [653]. Successive signs of toxicity observed were considerable preening, increased respiration which was deeper, closed eyes, and gasping respiration, lacrimation, and rhinorrhea and salivation. Animals appeared cyanotic and suffered short tonic convulsions and coma prior to death. In the same investigation, effects of chronic exposure were: inhalation of 6.35 ppm tetranitromethane by 2 dogs and 19 rats (with equal numbers of control animals) for 6 months on a 6 h/day, 5 days per week basis produced 11 deaths (57%) in the rats and no deaths among the dogs. Only one death occurred in the control group of rats. Temporary symptoms in the dogs after the first 2 days of exposure included occasional coughing, lethargy, unthrifty appearance and refusal to eat at the termination of each exposure. A yellowish discoloration of the fur persisted in all animals. There was occasional blood-tinged exudate on the nares of the rats. The target organ for chronic TNM toxicity was the central nervous system and heart. The time to 50% death in TNM-exposed rats was 36 min. at 1230 ppm, 60 min. at 300 ppm, and 518 h at 33 ppm [643]. At the highest exposure concentration, rats exhibited rapid and severe respiratory distress, which was followed by cyanosis, convulsion, coma, and death. Similar but less severe dose-related symptoms appeared at lower exposures. At 6.35 ppm, exposure for 6 h/day, 5 days/week, the ET50 was 133 days, and there were no specific signs of toxicity or alterations in blood chemistry.

Male Sprague-Dawley rats and CF-1 mice were exposed to TNM vapor generated by a diffusion tube system for 4 h. Groups of 10 rats were exposed to 6 concentrations between 10 and 23 ppm and groups of 10 mice were exposed at 8 concentrations between 14 and 76 ppm [647]. The LC50 values for rats and mice were 17.5 and 54.5 ppm, respectively. All exposed animals remained inactive and had breathing difficulties, and eye and nose irritation at toxic levels of exposure. Deaths that occurred following exposure were generally in the first 12 h. Rats at non-lethal exposure levels lost weight for 4 days but recovered weight gain by the end of the 14-day observation period. Weight loss was more severe in survivors at the higher (partially lethal) doses. Scattered weight losses were seen in surviving mice. The animals that died showed moderate to severe lung congestion and areas of alveoli hemorrhaging at necropsy. Survivors showed mild lung congestion. In the same test series, groups of 100 male Sprague-Dawley rats were exposed continuously for 14 days to 3.5, 5 or 7.5 ppm TNM by inhalation. No mortality was seen at 3.5 ppm; at 5 ppm, mortality at 10 and 14 days was 5 and 15%, respectively, and at 7.5 ppm mortality was 3, 23, and 65% at 7, 10, and 14 days. At termination, mean body weights of survivors were 15, 25, and 55% lower than controls at 3.5, 5, and 7.5 ppm exposure groups; mean wet weights of lungs were about 20, 35, and 65% greater than controls at the same exposure levels. No dose-related decreases were seen in liver or kidney weights. Lung irritation and edema were noted on gross examination. The incidence of lung edema increased with exposure level as did the severity of symptoms. Evaluation of pulmonary lesions was

complicated by chronic murine pneumonia in all animals in the colony. Bronchiolitis, bronchitis, and tracheitis appeared related to exposure. Based on decreases in body weight and increases in lung weight (edema), the lowest observed adverse effect level (LOAEL) was 3.5 ppm, but a no observed adverse effect level (NOAEL) was not established.

Rats and mice were subjected to inhalation exposure at 0.2, 0.7, 2.0, 5.0, and 10 ppm TNM in air for 6 h/day, 5 days/week for 13 weeks [648, 654]. At the highest dose tested, final mean body weights of male and female rats were 15 and 6% lower than controls, respectively. At necropsy, lungs were found infiltrated with mononuclear inflammatory cells with minimal fibrosis of the interstitium surrounding bronchioles. Focal metaplasia was found in 4/10 females at 10 ppm. These observations on lung pathology were not found at lower exposures. Increased mean absolute liver weights and liver to body weight ratios observed in both sexes were not dose-related nor was there any accompanying liver microscopic pathology. Mice exposed under identical conditions as rats displayed lethargy and dyspnea. The final mean body weights of males were 5 and 12% lower than controls at 5 and 10 ppm, respectively; in females weight loss was 9 and 12% at 5 and 10 ppm, respectively. Necropsy findings revealed mild inflammation of nasal mucosa, serous exudate, focal metaplasia of the nasal and bronchiolar epithelium.

In the same series of tests, life-time exposure studies also were carried out in rats and mice by exposing animals to inhalation of TNM in air at 0, 5, and 10 ppm for 104 weeks (2 years). The decrease in survival at the high exposure level was significant ($p < 0.001$). Mean survival time was 664, 660, and 616 days for male rats and 647, 691, and 657 days for females at 0, 2, and 5 ppm, respectively. Mean body weights at 100 weeks at 5 ppm were 17 and 15% lower than controls for males and females, respectively; at 80 weeks the weights were similar to controls in both sexes. Hyperplasia of the alveolar bronchiolar epithelium occurred at increased incidence in exposed rats, and in organs other than lungs no exposure-related non-neoplastic changes were seen. In all four test groups there was clear evidence of carcinogenic activity of TNM. In mice treated under similar conditions, mean survival time was 709, 650, and 633 days for males and 672, 688, and 673 days for females at 0, 2.0, and 5.0 ppm, respectively. Mean survival time was significantly lower ($p < 0.001$) in males exposed to 2.0 ppm. At 2.0 ppm exposure, the mean body weights at termination were 9 and 19% less than controls in males and females, respectively. Non-neoplastic lesions observed in the nasal passages of mice were similar but less severe than those observed in rats treated under identical conditions of exposure.

Groups of Fischer 344 rats and B6C3F₁ mice were exposed for 2 years to vapors of tetranitromethane at concentrations below (0.5 ppm) and slightly above (2 or 5 ppm) the current US recommended occupational exposure limit [655]. Under the conditions of exposure of 6 h/day, 5 days/week, tetranitromethane was found to cause mild irritation and hyperplastic lesions in the nasal passages, but no nasal cavity neoplasms. In contrast, nearly all animals exposed to the higher TNM concentrations, and the

majority of animals exposed to the lower concentrations, developed alveolar/bronchiolar adenoma or carcinoma. Squamous cell neoplasms of the lung also occurred in exposed rats. The extent of the lung tumor response, and the low concentrations of tetranitromethane required to bring about this response are significant, compared to effects of other toxic agents tested at the National Toxicology Program (NTP).

6.10.1 Carcinogenicity of Tetranitromethane

Dominant transforming genes were detected in lung tumors from rats and mice chronically exposed by inhalation to tetranitromethane [656]. The rat lung neoplasms were classified as adenocarcinomas, squamous cell carcinomas (epidermoid carcinomas) or adenosquamous carcinomas. The mouse lung tumors were classified as papillary adenocarcinomas or adenomas. In both species the tumors were morphologically similar to lung tumors in humans. Analyses indicated that the transforming gene was an activated K-ras proto-oncogene in both species. All of the rat tumors tested and all of the mouse tumors tested had a mutated allele with the GC→AT transition mutation present. Tetranitromethane may exert its carcinogenic action by both activation of the K-ras oncogene and stimulation of cell proliferation by its irritant properties.

6.10.2 Mutagenicity of Tetranitromethane

Mutagenicity of tetranitromethane was tested in *Salmonella typhimurium* strains TA97, TA98, TA100, and TA102, using the standard plate method or a preincubation method with or without S9 activation (0.5 mL rat S9/plate) [657]. Tetranitromethane was mutagenic in all strains. Activity was independent of an activation system with maximum mutagenic activity occurring at concentrations of 16–32 µg TNM/plate. Activation reduced the mutagenic and toxicity effect of TNM; at 130 µg/plate all strains except TA97 showed distinct mutagenicity without toxicity. Using the preincubation assay, background was reduced and maximum mutagenicity was seen (without activation) at 16 µg/plate. Strains TA100 and TA102 were sensitive to base-pair substitution mutagens, whereas strains TA97 and TA98 were sensitive to frame-shift mutagens. The results of these studies indicated that TNM reverts base substitution as well as frame-shift mutation.

6.10.3 Workplace Maximum Allowable Concentrations Established by Regulatory Agencies

The most likely occurrence of tetranitromethane (TNM) at the work place would be as a contaminant in TNT. The occupational exposure standard recommended by ACGIH (1981) for tetranitromethane was a TLV-TWA of 1 ppm (8 mg/m³). This limit has remained unchanged for several decades, although additional data have become available in the interim that indicate that TNM is a very toxic chemical with long-lasting effects.

AEGLs recommended by the National Advisory Committee for Acute Exposure Guideline Levels (AEGLs) for Hazardous Substances in 1999 were superseded by the more restrictive guideline levels issued in 2007 and listed in Table 52 for short-term exposure to TNM [658].

Table 52: Summary of proposed AEGL values for tetranitromethane.

Classification	30 min.	1 h	4 h	8 h	Endpoint
AEGL-1	Not recommended due to insufficient data				
AEGL-2	0.66 ppm (5.3 mg/m ³)	0.52 ppm (4.2 mg/m ³)	0.33 ppm (2.6 mg/m ³)	0.17 ppm (1.4 mg/m ³)	Pulmonary irritation in rats [647]
AEGL-3	2.2 ppm (18 mg/m ³)	1.7 ppm (14 mg/m ³)	1.1 ppm (8.8 mg/m ³)	0.55 ppm (4.4 mg/m ³)	NOEL for lethality in rats [647]

As of 2005, the NIOSH REL was 1 ppm (8 mg/m³). As of 2005, the OSHA PEL TWA for 8-h exposure remained at 1 ppm (8 mg/m³), in spite of the fact that in 2004 ACGIH had recommended a drastic lowering of the TLV/TWA down to 0.005 ppm and classified it as A3 chemical (confirmed animal carcinogen with unknown relevance to humans). The NIOSH IDLH limit was at one time 5 ppm, but later it was lowered to 4 ppm.

6.10.4 Protective Equipment for Handling of Tetranitromethane

Tetranitromethane is not absorbed by common filters in gas masks. It is a very symmetrical nonpolar molecule and passes right through high-surface area materials that effectively retain other molecules.

Nitrous Oxide

The topic of nitrogen oxides had to be distributed over seven chapters because it would have been a very large chapter, which would have made it more difficult for readers to find information on a specific compound. It would also have been difficult to distribute 30 chapters among 5 subvolumes and make each subvolume about the same size. That arrangement was made easier by dealing with smaller increment chapters. The other six chapters in this series are titled Nitrogen Oxides, Nitric Oxide, Dinitrogen Trioxide, Nitrogen Dioxide, Dinitrogen Tetroxide, and Dinitrogen Pentoxide.

Nitrous oxide, N_2O , CAS RN [10024-97-2], also called dinitrogen monoxide, nitro-gen(I) oxide, diazene 1-oxide, hyponitrous acid anhydride, laughing gas, or factitious air is the nitrogen oxide with the lowest state of oxidation of nitrogen, N^{+1} . In French, N_2O is called “*protoxyde d’azote*”. Nitrous oxide occurs naturally as the result of biological processes in the nitrogen cycle. Atmospheric air now contains 314 ppb N_2O . While fairly accurate measurements exist about the antropogenic increase of atmospheric CO_2 , there have been no such historic measurements for N_2O for the same time period since the beginning of the Industrial Age.

Nitrous oxide as the oxidizer in the hybrid rocket engines propelling the Scaled Composite/Virgin Galactic SpaceShipTwo, VSS Unity, to suborbital speeds has opened a new era of space tourism.

1 General Information on Nitrous Oxide

1.1 Summary and Review of Publications on Nitrous Oxide

A very comprehensive review of nitrous oxide chemistry was published in 2001, containing 329 literature references on various applications and reactions of nitrous oxide [1]. This is a good source of information for an in-depth study of this chemical. We have included several of those 329 references in our book here.

An excellent 17-page summary of properties and applications of nitrous oxide, including 145 references, was published in 2009 [2], but it failed to include the earlier published Leontev et al. [1] summary in its list of references. We have included several of those 145 references from the Gaidei [2] summary in our book here.

2 Preparation of Nitrous Oxide

2.1 Natural Occurrence of Nitrous Oxide

Nitrous oxide is the third most abundant minor constituent of the unpolluted atmosphere, exceeded in its concentration only by carbon dioxide. There are insufficient measurements of the historical evolution of nitrous oxide concentration in the atmosphere to decide whether anthropogenic nitrous oxide is a major contribution to global warming. Initially, there were more measurements of carbon dioxide than of nitrous oxide, but more recently sensitive remote sensing methods have been developed for nitrous oxide as well.

The analysis of air samples taken from air bubbles trapped in glacier ice demonstrated that the nitrous oxide content of the atmosphere remained rather constant (~280 ppb) over the past thousand years. From the mid-eighteenth century, the growth in industrial pollution caused a progressive increase in the N_2O content in the atmosphere. Presently, the concentration of N_2O in the Northern Hemisphere has reached 330 ppb and continues to increase at a rate of 0.5–0.9 ppb per annum. The nitrous oxide content of the atmosphere increases by 0.2 to 0.3% annually. Processes of nitrification and denitrification in soils of tropical and temperate regions and in oceanic waters are the major natural contributors of N_2O . It is assumed that these processes are responsible for 45–85% of all natural emission of N_2O . Heating and power plants, motor transport, some industrial chemical processes (12%), and agriculture (70%) are recognized to be the major sources of anthropogenic N_2O [1]. As of 2010, it was estimated that about 29.5 Mton of N_2O enter the atmosphere each year, of which 64% were natural and 36% due to human activity. Efforts to remove NO_x (NO and NO_2) from stack gases may inadvertently lead to the formation of the less visible, colorless N_2O as a byproduct. Nitrous oxide, ammonia, and methane are formed in manure piles under the action of ammonia-oxidizing bacteria. Some of the nitrogen fertilizer applied to agricultural lands in the form of ammonia or ammonium nitrate ends up as nitrous oxide in the atmosphere.

Carbon dioxide (“dry ice”) deposits have been identified on Mars and other extraterrestrial bodies. It is a safe assumption that wherever carbon dioxide deposits, such as in the polar caps of Mars, some nitrous oxide will deposit along with it. The formation of nitrous oxide, $\text{N}_2\text{O}(\text{X}^1\Sigma^+)$, in interstellar space and in ices on Pluto and Triton has been experimentally investigated. A molecular dinitrogen and carbon dioxide ice mixture was irradiated at 10 K with 5-keV electrons to simulate the electronic interaction effects of Galactic cosmic-ray bombardment of extraterrestrial ice samples over a time of 5×10^6 years [3]. By monitoring the experiment with an FTIR spectrometer on line and *in situ*, the temporal evolution of the 2235 cm^{-1} absorption band of nitrous oxide was found to follow pseudo-first-order kinetics; see Section 6, Environmental Impact of Nitrous Oxide.

2.2 Industrial Production of Nitrous Oxide

Nitrous oxide is commercially produced by controlled, slow thermal decomposition of ammonium nitrate:

Everybody knows that heating ammonium nitrate to beyond its melting point is a hazardous operation. There have been several industrial accidents when AN exploded instead of slowly decomposing during the production of N_2O [4]. The Compressed Gas Association has issued guidelines for the safe production of nitrous oxide by decomposition of ammonium nitrate [5].

In one version of the AN decomposition process, AN is decomposed in an aqueous, chloride-containing solution in nitric acid at 383–398 K (110–125 °C), while an ammonia atmosphere is maintained above the reaction mixture [6]. The atmosphere of ammonia is maintained by introducing at least part of the required ammonia into the gas volume of the reaction vessel. The decomposition of the AN and the formation of N_2O are enhanced by the presence of catalytically active ions of manganese, copper, cerium, lead, cobalt, and nickel, especially in their bivalent forms.

According to a similar patent, N_2O is produced by continuous decomposition of ammonium and nitrate ions fed into an aqueous, strongly acidic (4–6 M in H^+) reaction liquor containing 0.1–0.2M chloride ion as catalyst, at a temperature from 378–393 K (105–120 °C) [7]. The temperature is so maintained that the reaction liquor boils at the reaction temperature, the excess water being continuously removed. N_2O and water are continuously removed, and the N_2O gas that is withdrawn overhead is scrubbed with alkaline solutions to remove chlorine contamination.

A study of the decomposition of the aqueous ammonium nitrate at elevated temperatures and pressures as a function of chloride, nitrate, and total acidity showed that catalysis by both chloride and acid took place in solutions containing 20 mass-% NH_4NO_3 at 453 K (180 °C) [8]. Nitrous oxide and dinitrogen were generated in a 4 : 1 ratio below 0.2M H^+ . A mechanism based on the intermediacy of NO_2Cl was proposed for the chloride catalysis and contrasted to the radical-based pathways operational in molten NH_4NO_3 decompositions. Isotope labeling experiments using $^{15}\text{NH}_4\text{NO}_3$ led to the formation of ^{15}NNO -labeled nitrous oxide and the dinitrogen products $^{15}\text{N}^{15}\text{N}$ and $^{14}\text{N}^{15}\text{N}$ in a 1 : 3 ratio. Decomposition of $\text{NH}_4^{15}\text{NO}_3$ produced only $^{14}\text{N}^{15}\text{NO}$ and $^{14}\text{N}^{15}\text{N}$. This agreed with the reaction sequences:

A website shows pictures of equipment for production of N_2O by decomposition of ammonium nitrate in India [9]

A promising method for the production of N_2O is the thermocatalytic method of direct oxidation of ammonia by oxygen, where platinum-rhodium alloy, oxides of manganese, bismuth, cobalt, and others are recommended as catalysts:

However, the catalysts first proposed in 1928 were insufficient by activity and selectivity on the desired product (less than 84%), produced a high yield of unwanted NO, and were of low mechanical strength. It was, therefore, uneconomical to develop the industrial technology of production N_2O by this method. A process for the preparation of nitrous oxide by reaction of ammonia with oxygen in the presence of steam using a copper-manganese oxide catalyst gives a gas containing nitrogen, oxygen, and nitrous oxide, such that formation of unwanted NO_x byproducts is kept to a minimum [10–13]. Other catalysts patented for this reaction are ceramic mixed metal oxides [14]. For instance, a patent disclosed a process for preparing N_2O by catalytic partial oxidation of NH_3 with oxygen using a catalyst composed of manganese oxide, bismuth oxide, and aluminum oxide, which leads to dinitrogen monoxide with high selectivity [15]. The catalyst composition was: manganese(IV) oxide 5.0–35.0 mass-%, bismuth oxide 4.5–30.0%, and aluminum oxide 35.0–90.5% with a Brunauer-Emmet-Teller (BET) surface area of 5–80 m^2/g .

Many N_2O production patents recover N_2O from the off-gas of another chemical process where it can be directed to a useful purpose instead of venting it above the roof. For instance, the offgas stream of an adipic acid plant may contain from 0.8 to 1.0 mol of N_2O per mol of adipic acid formed by oxidation of cyclohexanol/cyclohexanone mixtures with nitric acid. Nitrous oxide is widely used for the selective oxidation of olefins and unreacted nitrous oxide can be recovered from the product mix and recycled [16].

It has been speculated that oxidation of ammonia by nitrous oxide under carefully controlled (non-combustion) conditions may even result in the formation of hydroxylamine.

2.2.1 Purification of Nitrous Oxide

Nitrous oxide produced by industrial processes may contain nitrogen, oxygen, and other oxides of nitrogen as contaminants, which need to be removed to obtain medical grade nitrous oxide. In a cylinder with nitrous oxide of inadequate purity, nitric oxide, NO, is released at the beginning of drawing gas from the cylinder, while contaminating nitrogen dioxide, NO_2 (in equilibrium with dinitrogen tetroxide) accumulates in the tank residue and is released when the tank is nearly empty. Nitrous oxide can be purified by distillation under high pressure [17]. The effective separation coefficients for nitrous oxide/impurity systems were determined experimentally. The distillation process at high pressure gave a very pure product.

Several other N_2O purification and separation processes have been patented. Another purification method liquefies the impure gas mixture first and then contacts it in

a bubble column with a countercurrent stream of a high-boiling, non-volatile organic solvent such as *N*-methylpyrrolidone, dimethylformamide, dimethyl sulfoxide, propylene carbonate, sulfolane, nitrobenzene, or dimethyl phthalate [18]. The presence of CO_2 in the raw feed gas would be desirable since it dilutes the otherwise potentially explosive mixtures in the first stage of the process. Because the physical properties of N_2O and CO_2 are so similar, it would be difficult to separate the gases by simply physical methods, but CO_2 can be washed out by an alkaline aqueous solvent.

A patent describes a process for purifying N_2O , wherein NO , NO_2 , CO_2 , and H_2O are initially removed, and the gas mixture is subsequently liquefied by compressing it from 40 to 300 bar and cooling to as low as 185 K (-88°C) [19]. From this liquefied gas mixture, dinitrogen monoxide can then be removed. Although this method achieves a purification and concentration of the N_2O , it is economically unattractive owing to the required high pressure (60 bar), the low temperatures 188 K (-85°C), and the associated high capital costs. Similar processes would be useful also for recovering and purifying nitrous oxide that has become contaminated during rocket cold flow testing.

3 Physical Properties of Nitrous Oxide

Several physical properties of nitrous oxide are very similar to those of carbon dioxide. Both molecules are linear molecules with a very small dipole moment and identical molecular mass (44). Both have a very narrow liquidus range, which makes it difficult to handle them in the liquid state without accidentally freezing the contents of tanks and lines.

A very good 22-page summary of physical properties of nitrous oxide was compiled in Appendix B of [20]. A more recent and very complete summary of the physical properties of nitrous oxide can be found in [21]. That report gives most physical properties as a function of temperature and is much more complete than the brief summary on physical properties of nitrous oxide offered here. It provides evaluated thermophysical properties data for nitrous oxide. Equations based on a critical evaluation of experimental data in the literature are given for the variation with temperature along the saturation line for the following liquid and vapor properties: density, specific enthalpy, specific heat capacity at constant pressure, dynamic viscosity, and thermal conductivity.

3.1 Physical and Mechanical Properties of Nitrous Oxide

The molecular mass of N_2O with a natural isotope distribution is 44.013 (1983 IUPAC atomic masses, compared to that of carbon dioxide, which is 44.010). NIST gives a molecular mass of 44.0128 for N_2O .

3.1.1 Freezing Point and Phase Diagrams of Nitrous Oxide

Table 1 gives a summary of literature data on the freezing (melting) point of nitrous oxide.

3.1.1.1 Phase Changes at Very High Pressures

The phase stability of simple molecular solids is generally predicated on a well-defined separation in energy scale between strong intramolecular interactions and relatively weak intermolecular bonds. A phase diagram for nitrous oxide was derived from *in-situ* high-pressure and temperature Raman and XRD studies [24]. Two new phases (II and IV) were discovered above 600 K between 18 and 50 GPa, and both were quenchable to ambient temperature. The crystal structures and stability fields of N₂O phases are similar to those of CO₂ below 50 GPa and 800 K. However, subtle

Figure 1: Schematic phase and reaction diagram of N₂O and [NO⁺][NO₃[−]]. (Republished and modified from [25], with permission from © 2005 Elsevier, permission conveyed through Copyright Clearance Center, Inc.) (based on data from several other sources)

differences in their physical properties and crystal structures were found to exist, indicating an increased disparity (or ionicity) between N—N and N—O bonds in bent N₂O-IV (*Pbcn*). At higher pressures and temperatures, N₂O disproportionates into ionic NO⁺NO₃[−] and N₂, whereas CO₂ polymerizes into an extended covalent solid.

Although feed pressures in rockets very rarely reach the gigapascal range, it is worthwhile mentioning that at very high pressures (10–50 GPa), N₂O undergoes several phase changes [25]. From atmospheric pressure to ~5 GPa N₂O crystallizes in the same configuration as CO₂ as Phase I (α) with *Pa3* configuration and above 5 GPa as Phase III (β) with *Cmca* configuration (Figure 1). Phases II and IV exist only above 23 GPa and 500 K.

At 10–30 GPa and with laser heating, N₂O disproportionates irreversibly into nitrosonium nitrate (similarly to the behavior of NO):

3.1.1.2 Melting Point at Very High Pressures

Like water ice, but in the opposite direction, the melting point of dinitrogen monoxide is pressure dependent. This dependency is similar to that of carbon dioxide, which has been investigated more thoroughly than dinitrogen monoxide. Up to a pressure of 25.25 MPa (250 atm), the melting point of N₂O follows the equation

$$T = 182.24 + 1.716 \times 10^{-1}p - 1.91 \times 10^{-6}p^2$$

where *T* is the temperature in kelvin and *p* is the pressure in atm [26]. The phase conditions of melting N₂O are similar to those of CO₂, which is why phase properties for both solids are listed together in Table 2 for comparison.

Table 2: Phase density near the melting point of nitrous oxide at high pressures.

Compound	Initial slope of (<i>dp/dT</i>) in atm/K	Volume change, cm ³ /mol	Phase density g/cm ³		$\rho_{\text{liquid}}/\rho_{\text{solid}}$ at melting point
			liquid	solid	
Carbon dioxide	45.9	8.05	1.178	1.501	1.274
Dinitrogen monoxide	58.3	6.075	1.229	1.480	1.204

3.1.2 Boiling Point of Nitrous Oxide

Table 3 gives a summary of literature data on the boiling point of nitrous oxide.

Apparently not only nitrous oxide by itself but also mixtures of nitrous oxide with ethane have been evaluated as refrigerants to replace fluorocarbons, which were the main refrigerants until their adverse environmental impact was recognized. Calculated binary interaction parameters were used to derive the vapor-liquid equilibrium for nitrous oxide/ethane mixtures, which revealed strong positive

deviations from Raoult's law with a positive azeotrope at around $X_{\text{C}_2\text{H}_6} = 0.65$ at $T = 243.15 \text{ K}$ [28]. We were amazed to read this publication and not find any precautionary note to warn potential users that this is a dangerous explosive mixture.

3.1.3 Density of Nitrous Oxide

Figure 2 is a representation of the density of nitrous oxide at very high pressures.

**Figure 2:** Density of liquid nitrous oxide at temperatures below 450 K. (Reproduced and modified from [20].)

Figure 3 is an extension of the data from Figure 2 to higher temperatures. One must anticipate that N_2O will start decomposing explosively under the conditions shown in this graph.

Figure 3: Density of liquid nitrous oxide at temperatures above 450 K. (Reproduced and modified from [20].)

The density and surface tension of liquid nitrous oxide were measured between 182 and 184 K, which is between the freezing point and boiling point of the liquid at atmospheric pressure and are tabulated in Table 4.

Densities of liquid N_2O were measured over a wider range with a high-temperature, high-pressure vibrating tube densimeter system in the sub- and super-critical states [32]. The uncertainty in the density measurement was estimated to be between ± 0.2 and ± 0.3 g/L, depending on the temperature. The densities were measured for temperatures from 473 to 273 K and up to 40 MPa for N_2O (251 data points), which encompassed density ranges between 0.1244 and 1.0511 g/cm³. The liquid densities were correlated with a new three-dimensional density correlation system (TRIDEN) to give a complete set of P - ρ - T data in the sub- and supercritical states and a virial-type equation of state.

The orthobaric density of a compound is the density of coexisting phases (liquid, gas, or solid) at a given temperature. Figure 4 shows the orthobaric densities of nitrous oxide in the temperature range from 183 K to the critical point, based on data points from multiple sources. The solid curve drawn through the numerous values passes well within the scatter of the literature data and joins smoothly with the low-temperature data:

Table 4: Density and surface tension of liquid nitrous oxide.

Data source: [31]

Figure 4: Orthobaric densities of nitrous oxide. (Reprinted and modified from [33] with permission from © 1961 American Chemical Society; permission conveyed through RightsLink.)

The orthobaric density data by Cook [34] (also shown in Figure 4 above as upright triangles, but the data point symbols are too small to recognize) can be expressed by the polynomial equations:

$$\rho_l = 0.452 + 0.00132(t_c - t) + 0.1232(t_c - t)^{\frac{1}{3}}$$

$$\rho_g = 0.452 + 0.00132(t_c - t) - 0.1232(t_c - t)^{\frac{1}{8}}$$

where ρ is the density, subscripts l and g signifying liquid and gas phase, respectively, t is the temperature in °C, and t_c is the critical temperature in °C.

A collection of 51 literature data points on the liquid density of nitrous oxide from five sources taken between 1929 and 1990 was curve fitted to give the following equation [30]:

$$\rho_l = \rho_c \exp\left(c_1 \tau^{\frac{1}{3}} + c_2 \tau^{\frac{2}{3}} + c_3 \tau^{\frac{7}{3}} + c_4 \tau^4\right)$$

where ρ_l is the density in g/cm³, ρ_c is the critical density, T is the temperature in kelvin, and T_c is the critical temperature in kelvin, $\tau = (1 - T/T_c)$, with the parameters $c_1 = 1.6779$, $c_2 = -0.5810$, $c_3 = 1.3148$, and $c_4 = -2.9806$. The standard deviation is ± 0.003 g/cm³.

Other measurements of the density of liquid N₂O showed that the density of liquid N₂O as a function of temperature in the temperature range from 280 to 293 K can be calculated from

$$\rho = 0.9368 - 0.0039t$$

where ρ is the density in g/cm³, and t is the temperature in °C. Another equation covers the density between 252.4 and 297 K:

$$\rho = 0.342 + 0.00166t + 0.0922\sqrt{36.4 - t}$$

A single data point for density at the boiling point at 183.75 K (−89.4 °C) was reported as 1.2257 g/cm³ [35]. See also [36]. The density of frozen N₂O at 78 K is 1.604 g/cm³, [37].

The density and refractive index at 543 nm of frozen nitrous oxide in comparison to frozen oxygen and N₂O₄ are summarized in Table 5.

Table 5: Density and refractive index of solid O₂, N₂O, and N₂O₄ deposited on a Si substrate.

Compound	Temperature, K	Density, g/cm ³	Refractive index at 543 nm
O ₂	16	1.54	1.322

N ₂ O ₄	16	1.17	1.316
N ₂ O ₄	60	1.90	1.548

Data source: [38]

3.1.4 Critical Point Properties and the Equation of State of Nitrous Oxide

The critical point properties of nitrous oxide reported during the past 150 years have fluctuated quite a bit, and there was a lot of data scatter due to the different experimental techniques used. The oldest critical point temperature ($309.5\text{ K} = 36.4^\circ\text{C}$) reported in the literature dates back to 1878 and was very close to the value generally accepted today. Table 6 gives a summary of literature data for the critical point properties of nitrous oxide. Because the critical temperature of nitrous oxide is only a few degrees above room temperature, it does not take much change of operating conditions to enter the supercritical regime where heat transfer and phase behavior are totally different from what we are used to for liquids below their critical point pressure and temperature.

The pressure-density-temperature (P - ρ - T) relations in the critical region ($0.996 < T_c < 1.004$ and $0.6 < \rho_c < 1.4$) were determined for N_2O by means of a direct

Note: Several of these critical point data were also listed on [43] NIST Chemistry WebBook website.

method [39]. The critical properties were determined from a logarithmic plot based on a power law for the vapor-liquid coexistence curve and the P - ρ relation on the critical isotherm for each system. The restricted linear model, one of the simplest scaled equations of state, was applied to describe the P - ρ - T relations in the critical region.

It is hard to believe that anyone would experiment with supercritical mixtures of nitrous oxide and methylamine (a perfect monopropellant and potentially explosive mixture) as a solvent for the extraction of lignin from wood. Given the explosive potential of this mixture, these experimenters were close to death without realizing it [40]. But it would have been interesting to use the same apparatus to characterize the supercritical $\text{N}_2\text{O}/\text{NH}_3$ system, which is also under investigation as a potential monopropellant.

The PVT properties of dinitrogen monoxide were measured by means of two different apparatus: one isochoric apparatus operating in the two-phase region, and the other a two-chamber apparatus operating in the superheated vapor-phase region [45]. The isochoric method was applied in the saturation region, and the Burnett two-chamber method was applied in the vapor region. Isochoric measurements were carried out at temperatures from 219 to 273 K and at pressures from 550 to 3100 kPa. The 18 measurements along the saturated liquid-vapor region were fitted, together with selected literature data, with the Wagner equation. For Burnett measurements, 14 runs along 7 isotherms in a pressure range from 170 to 5200 kPa were made. The second and third virial coefficients were derived, and good consistency was found after comparison with data in the pre-2004 literature. However, the Di Nicola third virial coefficients do not quite match with the set of virial coefficients published later by NIST and shown in Table 7. In a second set of measurements by the same investigators, PVT properties isochoric measurements were carried out at temperatures from 219 to 354 K and at pressures from 550 up to 5400 kPa [46]. For the Burnett measurements, 14 runs along 7 isotherms in a pressure range from 170 to 5200 kPa were performed. The second and third virial coefficients were derived, and good consistency was found after comparison with older literature data in the reduced temperature range of interest ($0.9 < T/T_c < 1.2$).

Numerous experimental values of the coordinates of the triple point and of the critical point of nitrous oxide reported in the literature were reassessed and those judged as most reliable selected for a statistical exercise [30]. Empirical equations were derived for the vapor pressure, sublimation, and fusion curves. The virial coefficients and saturation properties as functions of temperature along the equilibrium curves were described by reduced equations. They were then used in arriving at the molar enthalpies at the triple point and the normal boiling temperature. Equations for the sublimation and fusion curves resulting from the exactly integrated Clapeyron equation compared favorably with the results from the empirical treatment and the various experimental data. For the coordinates at the triple point, a molar volume value of $V_t = 35.847 \pm 0.002 \text{ cm}^3/\text{mol}$, temperature $T_t = 182.293 \text{ K}$, and $p_t = (87.866 \pm 0.001) \text{ kPa}$ were

selected from the average of six independent measurements taken over several years; see also [47, 29].

3.1.5 Compressibility of Nitrous Oxide

Deviations in the compressibility of real gases are indicative of molecule interactions and repulsion. The virial coefficients B of a simple equation of state

$$PV = RT + BP$$

were determined for gaseous nitric oxide and nitrous oxide [48]. The virial coefficient B of nitrous oxide in the range 197–298 K as a function of temperature and pressure can be expressed by the equation

$$B = 32 - \frac{5611.5}{T} + 3.9424 \times \frac{10^6}{T^2} - 3.9145 \times \frac{10^{11}}{T^4} + 3.0747 \times \frac{10^{15}}{T^6}$$

where B is the virial coefficient in cm^3/mol , and T is the temperature in kelvin. Later examination by other investigators showed that the Johnston and Weimer [48] values for N_2O were consistently too low, and for NO the values were consistently too high.

Other gas compressibility measurements covered the range from 243 to 423 K (–30 to +150 °C) for pressures up to 6.56 MPa (65 atm) [49]. Later measurements covered a wider pressure range from 6 to 315 atm [50, 51] Figure 5.

Figure 5: Compressibility factor of gaseous nitrous oxide. (Reprinted and modified from [33] with permission from © 1961 American Chemical Society; permission conveyed through RightsLink.)

From the same set of data, a graph with the pressure-volume isotherms was drawn (Figure 2 on page 230 of [33]).

Because the critical temperature of nitrous oxide is only a few degrees above room temperature, it is very easy to inadvertently slide into supercritical conditions. The pressure-volume isotherms of nitrous oxide near the critical point are, therefore, shown in Figure 6 for conditions near the critical point.

Figure 6: Pressure-volume isotherms of nitrous oxide near the critical point. (Reprinted and modified from [33] with permission from © 1961 American Chemical Society; permission conveyed through RightsLink.)

The compressibility of nitrous oxide gas was measured between 273 and 423 K (0 to 150 °C) and over a number density range of about 18 to 180 amagat¹, which corresponds to pressures of 1.616–16.66 MPa (16–165 atm) [52]. Attempts to measure compressibility of the gas above 423 K (150 °C) were foiled by incipient decomposition of nitrous oxide. The agreement with results of others [51, 33] using somewhat different experimental techniques was satisfactory. The virial coefficients were calculated, and the intermolecular potential of nitrous oxide calculated from the second virial coefficient for several forms of force laws, both spherical and non-spherical. It was attempted to see what information the virial coefficients can yield about the intermolecular forces that cause the deviation from ideal gas behavior. First, a spherical central-force model was used, and then an orientation-dependent model since N₂O is

¹ An amagat is a practical unit of number density. Although it can be applied to any substance at any conditions, it is defined as the number of ideal gas molecules per unit volume at 1 atm (= 101.325 kPa) and 0 °C (= 273.15 K). For nitrous oxide, one amagat unit of number density is equal to 4.4940×10^{-5} mol/cm³.

not a symmetrical molecule. A comparison with the physically similar molecule carbon dioxide showed some differences.

The physical properties of nitrous oxide and carbon dioxide are very similar in several aspects. The compressibility of carbon dioxide and nitrous oxide was measured at pressures under 0.2 MPa (2.0 atm) and over a temperature range of 243–348 K (–30 to –75 °C) [53]. Second virial coefficients were calculated and compared with data presented in the literature for both gases. The compressibility data were estimated to be accurate within $\pm 0.10\%$ of the actual compressibility factor.

The equation of state for a gas can be expressed in the form of a virial exponential equation

$$P = RT\rho[1 + B(T)\rho + C(T)\rho^2 + \dots]$$
